THE TREATMENT OF ACUTE RHEUMATISM.

By ROBERTS BARTHOLOW, M.D., LL.D.,

PROFESSOR OF MATERIA MEDICA AND GENERAL THERAPEUTICS IN THE JEFFERSON MEDICAL COLLEGE OF PHILADELPHIA, ETC.

IN a discussion of the treatment of acute rheumatism, the pathogenetic relations of the disease may seem to be a rather remote subject; but, to render my position clear, it is necessary to formulate, as briefly as may be, my conception of the nature of the rheumatic diathesis. The chemical theory which refers the joint troubles and the cardiac complications to an acid circulating in the blood, receives support from clinical facts and from the results of experiment. No theory can be true, however, which does not reconcile all the facts, and there are many which cannot be included in this chemical theory. There is an influence behind those chemical processes, which, in the so-called rheumatic diathesis, is concerned in the secondary assimilation to produce an excess of acid. That influence, we have many reasons for believing, proceeds from the nervous system. There are numerous facts which go to show that certain parts of the cerebro-spinal axis cause, when irritated, affections of the joints not unlike rheumatism. We owe more especially to Charcot¹ the accurate description of these joint diseases as they occur in connection with posterior spinal sclerosis, or locomotor ataxia. Long before Charcot's appearance on the medical stage, a neurotic theory of rheumatism had been propounded by that acute clinician, the late Prof. J. K. Mitchell, M.D., of Jefferson Medical College, Philadelphia. An account of his theory, based on the then existing knowledge of nervous pathology, may be found in a volume, prepared with a pious deference to a father's memory, by the more distinguished son, Dr. S. Weir Mitchell, of Philadelphia. It has happened, curiously enough, that the son has greatly enlarged the evidence on which the father's theory was based.

In his volume on "Wounds and Injuries of Nerves," Dr. Weir Mitchell gives many striking examples of joint troubles resulting from nerve and spinal injuries. Charcot, in connection with Joffroy,² Ball,³ Weir Mitchell,⁴ Buzzard,⁵ and others, have published numerous examples of arthropathy, in many features resembling the joint affection of acute rheumatism, only more severe and profounder in the depth and extent of the lesions. It is important to note in this connection that the joint changes of locomotor ataxia belong to the initial stage of tabes—to the stage of pains, and before the disorders of motility come on. It is evident, therefore, from this fact, that the spinal lesion is rather in the nature of an irritation. We may form a suspicion of the nature of the trophic lesions of joints due to centric affections by an examination of the nutritional changes wrought by irritation or inflammation of nerve-trunks. The data to be obtained on this point are very numerous. I can here hope to refer to the best-established facts as a groundwork on which to base my conception of the neurotic origin of rheumatism. In addition, then, to the

evidence furnished by the development of certain joint changes in the initial stage of tabes, we have some striking facts in regard to affections of joints produced by irritation of nerve-trunks. Thus, swelling of joints due to effusion has been observed in cases of neuritis. Indeed, Erb¹ affirms that these joint affections are in no way distinguishable from rheumatism. Friedreich,² in his monumental work, has collected a vast array of evidence showing the influence of nerve-inflammation on the nutrition of parts. Without occupying further space and time with this question, it may be affirmed that joint affections closely related to rheumatism are caused by certain spinal and nerve lesions, and hence we may regard it as probable, if not proved, that in the treatment of acute rheumatism we have to deal with a neurotic affection. Whilst it is a fundamental maxim in therapeutics to direct the remedies against the central lesion, the wise physician will not fail if he can remove the more prominent symptoms, for, in the present state of our knowledge, we are not often able to separate the lesion from its most accentuated symptoms in respect to the administration of remedies.

Having thus tried to establish the therapeutical diagnosis, the next point is to indicate the remedies which will supply the conditions thus furnished. There is no specific for rheumatism. We are, therefore, reduced to the necessity of proposing remedies for centric or peripheral nervous lesions, and for the more prominent symptomatic expression of these lesions.

No one can give anything like attentive consideration to the types of rheumatic cases without perceiving that they may be resolved into three groups, as regards the characteristics of the individuals composing them:

First.—Spare persons of considerable bodily vigor, good muscular development, and having a distinct family history of neurotic or rheumatismal disorders.

Second.—Obese subjects, addicted to malt liquors and good living, sometimes with—more often without—an inherited predisposition to rheumatic diseases: the gelatinous descendants of albuminous parents, as they have been entitled.

Third.—The feeble, pale anæmic subject, depressed by poor diet, and evil hygienic surroundings, including dampness and bad air.

No one can treat cases of rheumatism successfully unless he recognizes the type before him and adapts his remedies accordingly.

The first type is comparatively frequent, and found amongst the best elements of our mongrel population. Besides the inherited tendency, such subjects are prone to indulge in a rich diet of animal food, sauces, and wines, and to pursue rather sedentary occupations, or an indoor life. In these cases, salicylic acid, or the salicylate of soda, renders an incontestible service. It would be quite impossible to enter into details regarding this remedy's *modus operandi* just here, except to say that its antipyretic and antiseptic actions are quite inadequate to explain its curative effects in these cases of acute rheumatism. There can be little doubt that its curative effects are rather referable to its power to diminish the irritation of the trophic nervous system. There are, however, some practical details regarding its administration of great moment in respect to the permanency of

the results. It is quite certain that in this group of rheumatic cases, full medicinal doses of salicylic acid, or of the salicylates, will speedily arrest the pain and diminish the fever. The lowering of the temperature seems to bear a constant ratio to the diminution of the pain. It is not possible to express in figures with exactitude the doses necessary; the curative effect is attained by that quantity which reduces the pain and the temperature. In suitable cases, the administration of this remedy removes all of the more prominent symptoms and establishes convalescence in three or four days. Unfortunately, in a considerable proportion of cases, the disease manifests a strong tendency to relapse, after a marked subsidence of the acute symptoms apparently indicates the beginning of convalescence. A rule of practice has been distinctly formulated since this tendency to relapses has become well known. It is this: Give the remedy for several days after the acute symptoms have ceased. I have attempted, from my own experience, to give numerical expression to this rule, with the following result:

Salicylic acid, or the salicylates, should be given after the subsidence of the acute symptoms, and the cessation of the fever and pain, for the same number of days as the acute attack lasted. Thus, if the decline of fever and pain occurred on the fourth day, the remedy should be continued as many days thereafter, or for four days subsequent to the apparent cessation of the acute symptoms.

The manner of its action is by no means clear. The pain ceasing coincidently with the decline of the fever, and the joint swelling disappearing at the same time, indicate that the action occurs simultaneously, or that the one is a consequence of the other. It may be, that the remarkable relief afforded by salicylic acid and the salicylates, is due to the arrest of action caused by an antiferment; but it must be admitted that we are, as yet, far from a true explanation.

The second class of rheumatic subjects contains the obese, or those of full habit, the rotund addicted to malt liquors and to good living, all of whom are apt to suffer from a form of acid indigestion. The cases of rheumatism occurring in such subjects are, as a rule, much benefited by the alkaline treatment. This method is an empirical attempt to cure a disease characterized by an excess of acid in the various secretions. As the substitution of the alkaline remedies, for the spoliative treatment before employed, resulted in great benefit to these rheumatic patients, and as the system had an air of scientific precision, it is not surprising that it became widely popular, and that, until the salicylic acid treatment was introduced, unquestionably occupied the first place in the professional esteem. Dr. Fuller, the author of an excellent work on rheumatism, has been the most prominent advocate of the alkaline method. In a paper in the *Practitioner*,¹ he shows that much of the practice passing under that name, is not a proper application of the alkaline plan. As it is important to have a clear conception of the limitations of this method, I transcribe, from the paper referred to, Dr. Fuller's definition:

"By the 'alkaline treatment,'" says Dr. Fuller, "I mean a plan of treatment in which alkalies play an important part, but which consists not only in the administration of alkalies, but in the careful regulation of the secretions, the strictest attention to diet, and the administration of tonics, such as quinine and bark, as soon as the patient can bear them. . . . My practice is to give not less than an ounce and a half of the alkaline carbonates, either alone or in combination with a vegetable acid, during the first twenty-four hours of treatment. . . . More commonly two drachms are ordered to be taken in effervescence every three or four hours in combination with an ounce of lemon-juice, or with half a drachm of citric acid dissolved in four ounces of water. At the same time, if the bowels are torpid, ten

grains of colocynth and calomel pill [British Pharm.] are prescribed at bedtime. As soon as the urine, when freshly voided, ceases to show an acid reaction—which is usually the case after twenty-four hours—the quantity of the alkali is diminished by one-half, six drachms only being administered during the succeeding twenty-four hours. At the expiration of that time, if the urine remains alkaline, three drachms only are given in the next twenty-four hours; and on the fourth day, if the urine still shows an alkaline reaction, the form of the medicine is altogether changed. The treatment ceases to be essentially alkaline; either a cinchona draught is ordered to be taken three times a day, containing a scruple or a half drachm of bicarbonate of potash—a little more or a little less, according to the condition of the urine, which should be kept nearly neutral—or three grains of quinine dissolved in lemon-juice is given three times a day in effervescence, with half a drachm of bicarbonate of potash or soda. . . . The diet is restricted to beef-tea or broth, with soda-water and milk, and barley-water as a drink, as the smallest quantity of solid food, given a day before the tongue has thoroughly cleaned, is apt to induce a recrudescence of the disease. Wine and spirits are strictly forbidden, though experience has convinced me that wine and spirits prove less hurtful than the smallest quantity of solid food."

I have thus given the details of the alkaline treatment in the words of its chief promoter, at the risk of wearying my readers, because of a conviction that, in this country as in England, the method is very inadequately carried out. Considerable experience in it justifies me in saying that, in the class of subjects now under consideration, it is of the utmost value. Although relief to pain, the disappearance of the joint swelling, and the subsidence of the fever, are the evidences of improvement, no one who has had any considerable clinical experience with acute rheumatism, is unaware of the fact that relapses of varying severity, a tedious convalescence—slow repair of the damages—are to be considered in any just estimate of the relative value of different plans of treatment. That these cases are relieved by salicylic acid, is undoubted; but they tend to relapse, and the process of recovery is slow, often imperfect. In my experience, the special peculiarity of acute rheumatism in these obese subjects is the tendency to assume a sub-acute character and to be delayed in the progress toward recovery. They are also more liable to heart complications. The alkaline treatment, carried out as above described, gives better results in respect to relief to suffering, to duration of the disease, and freedom from complications. Stated numerically, the results, in my experience, may be compared with those of Dr. Fuller. "In ninety-four consecutive cases," says Dr. Fuller, "which were tabulated with a view to this inquiry, the average duration of the disorder after the commencement of treatment was only eleven days." Some statistics of Dr. Dickinson,² are even more conclusive: The tables embrace cases treated by venesection, by mercury, by salines, by salines and mercury, by a partial alkaline treatment, and by the true alkaline method. The number of cases of heart complication was greatest in those treated by venesection, being 50 per cent., and least in those treated by the true alkaline plan, being one in twenty-three cases, or 4.3 per cent. The average duration of the disease bore the same ratio, the minimum being those cases treated by the alkaline plan. At that time (1869) salicylic acid had not been suggested as a remedy for rheumatism—hence in the foregoing comparative statements, there are no cases treated by means of it.

If the relation between the action of alkalies and the neurotic disturbance called rheumatism, be demanded, we are not without resources for an explanation. Pflüger's phenomena of electrotonus were long ago ex-

¹ Vol. xi, p. 123: The Alkaline Treatment of Rheumatic Fever

² The Lancet, January 23 and 30, and February 6, 1869.

plained by Matteucci, and the explanation confirmed by Becquerel on the ground of the chemical action developed by the passage of the current. Humboldt was the first to show that the excitability of a nerve is increased by contact with an alkaline solution, and diminished by contact with an acid solution. Now, as the condition called rheumatism may signify a depressed state of the trophic functions, the good effects of alkalies are at once apparent—that is, the increase of the functional activity—and thus counteract the depression.

Besides the administration of the alkaline remedies, there are other therapeutic questions to be answered in respect to the treatment of the second group of rheumatic subjects; but these will be more properly considered hereafter.

The third type of rheumatic cases and numerically the most important; probably, also, pathologically, the most serious, is the feeble and anæmic subject. A rheumatic of this kind is pale, rather thin, the muscles weak and wanting in firmness, the chest narrow and somewhat flat, the joints prominent and lax. In such persons an extension of the rheumatic inflammation from joint to joint, until almost all the joints of the body are involved, is to be feared, as it is of frequent occurrence. Cardiac complications are relatively frequent. It need hardly be observed that in such subjects the depressing effects of salicylic acid and of the alkalies are to be dreaded. Here clinical experience is in entire accord with theory. We owe to Dr. Russell Reynolds, of London, the introduction of a remedy for acute rheumatism, which is especially suited to this group of cases. I refer to the *tincture of the chloride of iron*. To be effective it must be given in full doses—from ʒ ss. ʒ j. in sufficient water every four to eight hours. It lessens the swelling and pain of the joints, lowers the fever, diminishes the tendency to heart complication, and, above all, sustains the vital powers in their struggle against the encroachments of the rheumatic disease.

I am far from denying that cases of rheumatic fever in these anæmic subjects would not be relieved by salicylic acid, but I do affirm that so much depression would result that relapses would occur, and the convalescence would be prolonged owing to the remarkable depression of the nutritive functions. The same state of things results from the administration of alkalies. The blood is spoiled, the heart enfeebled, and complications of various kinds invited. On the other hand, very conspicuous benefit results from the vigorous administration of the tincture of iron. Besides its influence over the course of the disease—shortening its duration by checking waste, and preventing complications by maintaining the vital resources—the tincture of iron, as shown by the late Dr. Anstie, has a distinct prophylactic effect, so that, when an attack is threatened, it will, by timely administration, prevent it.

During the period of convalescence from acute rheumatism, after the treatment by salicylic acid and by alkalies, the tincture of iron in the full doses already advised renders an important service. The tenderness and effusion about the affected joints, the subfebrile temperature, and the condition of anæmia, are alike greatly improved by its administration in efficient doses. I have repeatedly observed that cases which lingered long on the hands of the physician after the acute symptoms had subsided, quickly improved and recovered when efficient doses of the tincture of iron were administered, and, at the same time, suitable blisters were applied to, or about, the affected joints.

Independently of the considerations above expressed regarding the utility of blisters, the "blister treatment" of acute rheumatism is deserving of careful consideration. Blisters in various ways, and applied in accordance with various notions, have long been used in the treatment; but the "blister treatment," properly speaking, of acute rheumatism has been systematized by Dr. Davies, of the London Hospital, and Dr. Dechilly, of France. The

latter, however, applied a large blister to cover the joint, and permitted it to remain on until sufficient inflammation occurred to produce abundant serosity. Dr. Davies, on the other hand, was content to apply the blisters around rather than on the joint itself. It is a remarkable fact that blistering brings about a neutral or alkaline condition of the urine, how acid soever it may have been before the blisters were applied. More or less strangury occurs in some instances. So remarkable is the relief to pain produced by the blisters that patients petition for their renewal from time to time. Cardiac complications are comparatively infrequent, and the duration of the disease is reduced to the limits of the favorable cases. Indeed, I may sum up the testimony as to the efficiency of this method in the words of Dr. Greenhow, who affirms that the treatment of rheumatism by blisters is quite as successful and less objectionable than by salicylates.

The good effects of the blister treatment afford a strong justification of the neurotic theory. When first ascertained, the result was ascribed to the withdrawal of a quantity of acid serum from the neighborhood of the affected joints. The change in the character of the urine, induced by successive blisters, rendered further explanation necessary. The increase of our knowledge respecting the influence of peripheral irritation on the state of the nerve-centres, and especially on the trophic system, has paved the way to a better appreciation of the facts; nevertheless the final explanation remains to be made.

A combination of the blister treatment with salicylic acid, with alkalies, or with the tincture of iron, may often be made with signal advantage.

The importance of a proper diet is not less than is stated by Dr. Fuller in the quotation made from his paper. Solid food should not be allowed in any case. Liquids composed of starchy and saccharine matters are only less hurtful. Milk and animal broths are the articles to be depended on chiefly until the cessation of all joint troubles will permit the gradual restoration of a solid dietary. Lemonade and carbonic acid water are allowable, unless they produce flatulence, when they will excite fresh joint mischief. Anodynes are to be avoided if possible; when necessary, atropine is preferable to morphine, if adequate to relieve the pain, which it usually succeeds in doing. The complications which may arise in the course of rheumatic fever demand more careful treatment than I can give them at the conclusion of this article.

THE SIGNIFICANCE OF TEMPERATURE AFTER OVARIOTOMY.¹

By CHARLES S. WARD, M.D.,

ATTENDING PHYSICIAN NEW YORK LYING-IN ASYLUM; ASSISTANT SURGEON WOMAN'S HOSPITAL, ETC.

So much has been written on ovariectomy and the care of patients after that operation, that to some of you I fear the subject will appear hackneyed; to others I hope the short consideration of certain points in the diagnosis and treatment of conditions arising after, and, for the most part, due to that procedure, may not be without interest.

It will be impossible, in the brief time allotted, to do more than epitomize even a few points in the after-treatment, nor will it allow of illustrative cases.

Ovariectomy may be one of the simplest operations in the whole domain of surgery. On the other hand, it may be, and often is, one of the most difficult. At times it presents such problems for solution as to demand not only the calmest judgment, but that acquaintance, personal and traditional, with what has been done in similar cases, which we call experience, in order to give the patient the best possible chance for recovery, or to exorcise the operator from some serious dilemma. So also the after-treatment presents its problems, some of which we shall attempt to solve.

¹ Read before the New York Practitioners' Society, December 1, 1882.

With the completion of ovariectomy the operator's anxieties are but just beginning. Although they may exist actively during that procedure, he is in a position to deal promptly with complications which he can see, and which develop, so to speak, under his hand. He is then in a more special degree the active agent, controlling the *physical* conditions which he meets or creates; while *after* the operation he has to wait upon certain *vital* forces, which are variously modified by age, temperament, the physical condition of the patient, and the traumatism in each individual case. These factors exhibit themselves in unequal proportions and give color to the case as one or the other predominates.

In order to intelligently conduct a case we should have a clear idea of the processes set in operation by our surgical interference, that we may know in what direction to expect this or that manifestation and its import, and be ready to meet unfavorable symptoms at their very inception.

For practical purposes we may separate all cases into two classes:

First.—Simple cysts with few or no adhesions.

Second.—All other ovarian tumors, whether cystic or solid, having such parietal or visceral attachments as to necessitate much injury to surrounding structures on detachment, or whose contents are in themselves irritating or of such a character (thick colloid) as not to be readily removed from the peritoneal cavity, should they escape into it.

In the first class, assuming that by dexterous operation and careful ligation we have secured ourselves against shock and hemorrhage, there remains ordinarily but one source of *danger*—peritonitis—and that from the limited abdominal incision or the severed pedicle.

In the second class our list of dangers is largely increased, the principal ones being: 1. Shock: due to actual severity of case from violence done; due to hemorrhage; due to unnecessary and prolonged exposure from indecisive procedure. 2. Hemorrhage: From pedicle; from severed adhesions; from viscera from which adhesions have been torn; from hemorrhage occurring within the pedicle from incautious traction. 3. Peritonitis: visceral, parietal. 4. Septicæmia with concomitant peritonitis. 5. Cellulitis.

I have mentioned but five sources of elevation of temperature. There are others, but I speak of the principal and usual ones.

Shock and hemorrhage we shall not discuss, they being not included in the limited range of this paper, which deals with the inflammatory processes and their order of manifestation.

Each of the above conditions, except shock and hemorrhage, expresses itself by an elevation of temperature; but, as is known to all, the value or import of the same degree of elevation of temperature is quite different, according to whether it be due in the one case to a peritoneal or a cellular inflammation; hence the great importance of an early and correct diagnosis of the condition developing, as manifested by increase of temperature. In one case, the cellular, we may rest at ease, quite sure of the competency of nature to bear without risk a certain elevation, and equally sure of a limitation; while in another—the peritoneal—we have with no greater elevation, perhaps, a constant menace, if not from the violence or area of inflammation itself, from failure of a very impressionable ganglionic system induced by that inflammation.

In differential diagnosis we are greatly aided by the time which has elapsed since operation, when the elevation of temperature first manifested itself, as well as the character of the case. If simple, with no adhesions, and no accident has occurred, or unnecessary invasion of the peritoneal cavity by the operator's hands or instruments, we have ordinarily but one source of danger, that from peritonitis, and we know, as a matter of clinical experience, that such a peritonitis would necessarily manifest

itself within seventy-two hours, and usually within forty-eight. But suppose, in such a case, from the fourth to the sixth day, and even many days later, we have a beginning elevation attended by some pain, not colicky, and tenderness, with absence of tympanites, what are we to expect usually? Not a peritoneal inflammation, for that is prompt in declaring itself, as the peritoneum is quick to resent any injury. We must look for causes extra-peritoneal, inflammation in a less impressionable tissue, namely, the areolar tissue, and that, too, in the abdominal wall alongside of the incision. Now this is readily determined by gentle palpation and inspection. The abdomen will usually be found soft in the iliac region; but as the fingers approach the median line they will appreciate that there is more firmness, if not already induration, which might, from the fact of the line of incision running between the recti muscles, give rise to a longitudinal cellulitis, thus suggesting, perhaps, that it is one or the other recti which is felt. The error will at once be corrected when we remember that at such a time the recti are not as readily detected, owing to their laxness from long stretching by the tumor. We shall also be aided in our diagnosis by the expression elicited from the patient, who will complain of this or that point as being tender to the touch; these points will generally be at or about the sutures. Later on, one may see an asymmetrical elevation of the abdominal wall, caused by the cellulitis. Having discovered these indurations we may dismiss much of anxiety from our mind, as it is the areolar tissues above the dense transversalis fascia which are involved, and yield more readily than it to the pus which almost invariably seeks an outlet alongside one or more of the sutures.

In the treatment of such a condition as just related, we should seek, by prudently abundant diet, to sustain the patient, having no fear, as in peritonitis, of exciting peristalsis, to the great injury and suffering of the patient. Abscesses in such cases have usually but small influence on the general progress of the case, are usually limited in area and duration, being the result of a surgical injury, and not of pyæmia. As to temperature, it usually ranges from 100.5° to 102° . Local applications are rarely needed, though warmth is often agreeable, and may be applied by means of spongio-piline, wrung out of hot carbolized water, poultices, the hot water bag, or the hot water coil—quite the opposite in principle to the treatment of peritonitis, as will be seen. Resort to the bistoury in such cases is rarely necessary, as pus very rarely forms before time for removal of the sutures on the eighth or ninth day, and it is through the tract of the sutures that pus escapes.

Our study of the peritonitic inflammations will be aided later on by the march of symptoms, as portrayed in a simple uncomplicated recovery after ovariectomy. In such, during the first twelve or fifteen hours, the intoxication and vomiting occasioned by ether—the latter perhaps increased by the morphia given—are usually the only disagreeable symptoms. There is acceleration of pulse from ether stimulation, with a range of from one hundred to one hundred and thirty per minute, the skin remaining cool, temperature 99° to 100.5° . After lapse of the time mentioned the temperature varies but little, reaching perhaps as high as 100° during the first twenty-four hours, then dropping down to 100° or 99° , there to remain, or tending to approach more nearly still the normal as time advances. The dressings and sutures may be removed on the eighth day, when, if the abdominal walls are thin, we may expect to find a perfect line of union, and have now to wait but a few days before our patient is quite well, so far as the operation is concerned.

The two great sources of elevation of temperature in tumors of the second class are peritonitis and septicæmia. It is an interesting clinical fact, that many of the worst forms of tumors, whose attachments to the parietes, deep in the pelvis, and even omental and intestinal, are so firm and universal, seem to escape peritonitis.

Whether this is due to the fact, as I believe, that the peritoneum has not only lost its special intolerance of intrusion, but even its distinctive anatomical structure, I cannot here discuss. Be this as it may, there are many such cases where the violence done is so great as to make one say at once, this patient must certainly die of peritonitis, yet we often see such cases make rapid and perfect recovery with a thermometric range not having gone above 101° F., and where, as I believe, the repair of injury done is more like that following an injury to the areolar tissue, possessing clinically none of those evidences which we regard as characteristic of peritoneal inflammation. But in such cases where *peritonitis* does declare itself after operation, it is usually within the twelve or fifteen hours immediately after. There is no chill, but within that time the temperature has steadily risen to 101° : the stomach rejects the little fluid received; the pulse continues high, and must not be mistaken for that of ether stimulation. *Pain* may be complained of, but is not necessarily present, I suppose, from the fact that the abdominal walls are so lax, that the friction of peristalsis is reduced to a minimum, and that often the peritonitis begins as pelvic, affecting the parietal layer, the least impressionable by reason of its more passive state, so that the visceral, especially the intestinal, is not affected in this variety. Generally within ten or twelve hours more the temperature has risen to 102° to 103° ; some tympanites now shows itself, while the nausea is increased and the pulse continues its high range. In patients of apparently good constitution this condition may last three or four, or even five days, with progressive severity of symptoms. The facies then begin to express the serious impression made upon the system; dark rings encircle the eyes, which become sunken; the pulse becomes more and more rapid, while the increasing tympanites embarrasses the respiration, making it shallow and thoracic; the tongue is dry and parched, the mind wanders, and the final collapse occurs. Such is the usual march in pronounced cases; in others the patient will be seen to lose ground from day to day with little elevation of temperature, and yet on autopsy will present evidence of intense peritonitis. I mention this variety, as one inexperienced in the peritonitis following ovariectomy might be quite unaware of the peril of his patient.

You will notice that I spoke of peritonitis in this class of cases, as beginning promptly, though perhaps not announcing itself by violent pain or excessive temperature. It is in reference to the time in differential diagnosis that I would call your attention. It announces itself too early for mural cellulitis, and too early for septicæmia usually, and the time of announcement should be for us positive and pathognomonic of the condition, and should urge us to immediate efforts to control at its very inception a process so dangerous. Now the resources at our command are unfortunately mainly but two—morphia to control peristalsis and the pain induced by it as well as from the traumatism. This must be given to absolute relief from pain, not suffering the patient to be conscious of such for one moment, in order that that element may not be the one to destroy the repose of the patient. A more important matter of treatment is the application of cold to the abdomen, which is best made by the rubber tube coil laid upon the abdomen, through which a continuous current of ice-water flows, or by the use of the Kibbee cot, the latter a very disturbing and troublesome method, and one, as I have almost uniformly seen, provocative of diarrhœa. The application of the coil should be resorted to, where the character of the case is one to warrant the belief that peritonitis will be excited, just as soon as the temperature reaches 100° , and the effort made to keep it, the temperature, there. If peritonitis is to be controlled by this means it must be taken at its very inception, and before it has impressed the ganglionic system. We must protect the patient from the danger due to the high temperature, regardless that there comes a time when control of temperature is of no

avail, and that the patient sinks from peritoneal changes or failure of ganglionic system as before mentioned. In the early application of the coil we employ it as a true antiphlogistic. I do not say that cold will cure peritonitis or always prevent it. I believe, intelligently applied, it often does so modify its severity as to give the patient a chance for recovery when it might have gone beyond control.

I have thus far spoken of pure traumatic peritonitis, if you will let me for the time so call it, in contra-distinction from septicæmia with concomitant peritonitis.

Septicæmia, as a rule, appears later than uncomplicated peritonitis, beginning very like it, and usually more or less complicated by it. The temperature is usually *early* more uniform or expressive of a mild inflammatory process, for the reason that it takes some little time to establish the condition septicæmia, for nature is not overthrown at one blow in this more than in other diseases; but once let that condition be established, and then but a small septic absorption, be it continuous, is sufficient to maintain it. Its usual period of manifestation is from the third day on, and the usual picture is the following: A patient with a temperature which has not gone above 101° to 102° , whose stomach has not behaved badly begins to show an increase of temperature, irritability of the stomach, rapidity and feebleness of the pulse, developing tympanites, and then a peculiar hue spreads over the face, one hard to describe, something between a bronze or coppery hue, the result of a vaso-motor paralysis. This peculiar hue in such cases cannot be mistaken by one familiar with it. The eyes sink, the tongue becomes at times red and very dry, at others dry and brown, at times the eyes appear jaundiced, and such a tint sometimes overspreads the body; but *the* usual hue is the one mentioned, and called, for want of a better descriptive name, coppery. If we follow the stage out, diarrhœa—a most usual accompaniment of septicæmia—appears, and vesical irritation, when septic fluids bathe its inverting peritoneum, delirium of a very mild type (I am now speaking of ovariectomy cases), and lastly coma, blueness of skin, and death. I spoke of increased temperature manifesting itself usually about the third day; it may appear before. It usually announces *itself then* by a rapid elevation, followed at times by equally as rapid a decline. When abdominal drainage is practised by proper drainage-tubes in efficient hands, it is marvellous at times to see the effect of removal of septic fluids from the cavity through the tube, and the long continuance of moderate temperature when that well into which the tube enters is thoroughly washed out with either pure or carbolyzed water. The cases which recover from such abdominal drainage are septic cases, due to decomposing fluids which have oozed from disrupted vessels from various sources, or from ovarian fluids not of the dense colloid variety; in other words, fluids which will gravitate to the well which the drainage-tube occupies. Unfortunately where there has been an escape of dense colloid material, drainage accomplishes but little, and septicæmia once established, as it surely will be, is fatal.

In the curable forms of septicæmia our aim must be the removal of septic fluids, control of temperature by the coil, relief of pain by morphia, and cautious administration of nutriment either by stomach or bowel.

The limits of this paper will not allow of a full description of any of the inflammatory complications; its purpose is to show that there ought to be no uncertainty in the mind of the clinician as to the origin and time of manifestation of the *usual* manifestations after ovariectomy, and that certain definite resources are at his command.

Now there are other sources of elevation less important, but complicating the diagnosis. Among these are menstruation, cystitis, nephritis, and rarely subacute tetanus, to say nothing of intercurrent diseases, particularly malaria, pneumonia, and as the result of either and exposure, bronchitis. The possibility of the occurrence of

these should be borne in mind, and in doubtful cases carefully eliminated.

To sum up, simple cases, where the injury done is only the abdominal section and severance of pedicle, admit, usually, of but two manifestations—peritonitis and mural cellulitis.

The peritonitis will surely manifest itself before the expiration of forty-eight, or at most, seventy-two hours; after the expiration of that time any elevation due to operation will be due to mural cellulitis.

In cases of the second class, peritonitis may begin at once, and still recovery take place promptly; while an elevation which begins after the third day either announces *septicæmia* or septo-peritonitis, or the more harmless mural cellulitis, according to symptoms, the differential points of which have been alluded to.

As a matter of course, either of the above conditions may encroach somewhat upon the limits of the other, but the main fact, the time of manifestation of each, remains.

I have given no space in this short paper to the discussion of the merits of quinine as an antipyretic in septicæmia, for it avails very little and must not be relied on as such; the septic material must be removed, and cannot be counteracted or neutralized by this or other so-called antipyretics, though they may do something toward maintaining the system in a general way. A fuller consideration of matters germane will shortly be published.

THE ABSORPTION OF NUTRIENT ENEMATA.¹

By CHARLES L. DANA, M.D.,

NEW YORK.

THE physiological process by which nutrient enemata are absorbed is still a matter of dispute. Three theories are offered: First, that the food is digested by ferments which have descended from the upper parts of the alimentary tract; second, that the food is carried back by "retrostalsis;" third, that it is digested by a local process.

First.—The theory of the descent of ferments is quite untenable, because the gastric and pancreatic ferments are secreted intermittently and only upon local stimulus; and further, because it is made quite probable by the experiments of Langley that these ferments are destroyed before they reach the colon.

Second.—Dr. Henry F. Campbell, of Georgia,² has advocated with much force the theory that there is a reversed peristaltic motion, or as he terms it, "retrostalsis," which carries the injected food into the small intestine, where it meets some of the digestive secretions.

Considerable plausibility was given to this theory by the interesting experiments of Professor Hal. C. Wyman, of Detroit.³ He injected two dogs, one living, the other dead, with a pint and a half of colored milk; and found that in each case the milk passed up the whole length of the small intestine. In two other living dogs he injected four ounces of colored milk, and found that the fluid passed up to the middle of the duodenum in one, and to the middle of the jejunum in the other. A fifth dog was injected in the same way. A portion of the milk was immediately rejected. The remainder passed no farther than the ileocaecal valve. In the case of a man with a fistula in the colon and another in the ileum, it was found that half a pint of milk injected into the rectum was carried to the ileocaecal valve, "and probably farther."

In further support of the theory of retrostalsis, are some clinical facts which show that, sometimes at least, enemata may pass back into the small intestines,⁴ or may even reach the stomach and be vomited.⁵

Before commenting upon these I will record my own experiments.

First.—Took a fifteen-pound living dog; injected one-

half ounce carmine-colored milk. Examined two and one-half hours later: Staining half way to ileocaecal valve.

Second.—Ten-pound dog, living (as were all those experimented upon). Injected as in first. Half hour later: Staining to ileocaecal valve.

Third.—Ten-pound dog. Injected as above. Bowel full of feces. Half hour later: Could not detect any passing back of the fluid.

Fourth.—Fifteen-pound dog; injected as above. Two and one-half hours later: Most of milk in last half of large intestine; slight staining *just above ileocaecal valve*.

Fifth.—Twelve-pound dog. Injected one ounce of carmine-colored milk. Two and one-half hours later: Bowel full of feces; nothing above the ileocaecal valve.

Sixth.—Fifteen-pound dog. Injected as in fifth. Two and one-half hours later: Some milk had passed *eight to ten inches above ileocaecal valve*.

Seventh.—Ten-pound dog. Injected one-half ounce carmine-colored milk. Two and one-half hours later: Milk had gone up only a little distance; large amount of feces in the bowel.

Eighth.—Ten-pound dog. Injected two ounces of colored milk with some force. Two and one-half hours later: *Injection had passed up into the stomach*.

Ninth.—Twelve-pound dog. Injected one-half ounce carmine-colored milk. Three hours later: It had passed half-way up large intestine.

Tenth.—Ten-pound dog. Same as ninth.

Eleventh.—Twelve-pound dog. Same as ninth.

Twelfth.—Ten-pound dog. As in ninth, but injection went to ileocaecal valve.

Thirteenth.—Fifteen-pound dog. Same as twelfth.

Fourteenth.—Ten-pound dog. Injected two ounces iodized starch and water. Two and one-half hours later: Injection went *a little way beyond ileocaecal valve*.

Fifteenth.—Twelve-pound dog. Injected one ounce colored milk. Three hours later: It had not gone beyond ileocaecal valve; bowel full of feces.

Sixteenth.—Fifteen-pound dog. Previously had given a cathartic which produced a passage. Injected one ounce colored milk. Three hours later: It had not gone above the ileocaecal valve; bowel not empty.

The injections were given with an ordinary hard rubber syringe, and no especial force was used.

There was a source of error in Dr. Wyman's experiments, in that he used very large injections. Even my own were proportionately very large, two or three drachms being as much for a dog weighing ten pounds as four or five ounces for a man.

My experiments therefore showed:

First.—That large injections, forced in, *may* cause a "retrostalsis" which will carry the mass by the ileocaecal valve and even into the stomach.

Second.—That ordinary nutrient injections of two, three, or four ounces, pass back some distance,⁶ and may even reach the ileocaecal valve, but do not go farther.

Third.—That the injection is carried back much better when the lower bowel is empty, or comparatively so.

The few clinical observations which show that retrostalsis can take place, show also that it takes place only under peculiar conditions, such as intestinal obstruction, the use of large, forced or very stimulating enemata, inverted posture, etc. The assertion of some patients that they taste the food given by enemata proves nothing.

Since we cannot explain the absorption of enemata by retro-peristalsis, it must be that the process is local.

It is an established clinical and physiological fact that nutrient enemata are absorbed. Bauer, for example, found that in dogs enemata of pure albumen and acidulated or saline meat were absorbed. In my cases about one-half of the milk injected was absorbed within three to four hours. The colon is quite vascular and has a large supply of lymphatics. It is not an excreting organ, as stated by Dr. D. W. Bliss, but its function is to absorb. In soli-

⁶ Dr. A. H. Smith has shown this to take place in human beings.

peds it has a powerful digestive function. The secreted juice has in man a feeble proteolytic power (Eichorst).

Albuminous food, when injected, speedily undergoes chemical changes and decomposition. In some of the early stages of this process it is quite possible that the changed albumen passes into the surrounding vessels. Normal peptic digestion is only a decomposition with many stages in it, during some of which the albuminous matter is absorbed. It is not necessary that albumens be made perfect peptones before they can diffuse into the blood-vessels and lymphatics.

Fats cannot be absorbed to any great extent in the colon or rectum. It is not necessary to inquire whether starches can be changed to glucose, since it is always possible to add some form of animal sugar to the enema if that be thought necessary.

So far as my clinical experience goes, injections of milk and beef-tea, especially the former, are very nearly as effective as the peptonized preparations, especially those prepared with acid and pepsin. Dr. Bliss has published some cases which seem to show that mixtures of peptone and beef extracts are very effective. Such mixtures were recommended twelve years ago by Leube and M. Mackenzie, but they are costly. Doubtless solutions of the powdered meat or milk, as used by Debove and Dujardin-Beaumetz, would be useful. I have been unable to convince myself that there is any magic in peptone preparations or that they are absorbed much more rapidly than carefully prepared and finely divided meat preparations.

ON THE

DIAGNOSTIC VALUE IN PREGNANCY OF VARIATIONS IN THE FREQUENCY OF THE PULSE DUE TO CHANGES OF BODILY POSITION.

By H. D. FRY, M.D.,

WASHINGTON, D.C.

IN June last Jorissenne stated (*Archives de Tocologie*) that he had discovered a new sign of pregnancy, and claimed to have been able by its means to diagnosticate the presence of that condition when there existed no other corroborative evidence than the missing of a single catamenial period.

According to his observations, and contrary to the physiological law, the radial pulsations during pregnancy number the same irrespective of the woman's position at the time of examination. He directs that the pulse should be counted "for the space of fifteen seconds whilst the patient is standing, then sitting, and then reclining. The order may then be reversed, and uniformly the same number of beats will be recorded."¹

The publication of this observation has attracted the attention which the importance of such a statement is sure to demand. It is especially in the first months of gestation that the physician stands in need of reliable evidence to assist him in the recognition of its existence. At present he can, alas! in too many cases, only state the *probabilities* and await the sequence of an uncertain prediction which is to bring either happiness or sorrow to the unfruitful wife or sinning Eve. For this reason we should endeavor to add to the means already at our disposal any symptoms indicative of the presence or absence of a fecundated ovum within the uterine cavity; and, when such a one is found, to ascertain its comparative value and appreciate it accordingly. By doing this we may throw some light upon the subject of diagnosis and prevent ourselves from being led astray by the uncertain glimmer of an *ignis fatuus*.

Shortly after reading a notice of Jorissenne's experiments I had an opportunity to test the sign in a young woman who was fearing the consequences of having yielded to advances made soon after the cessation of her menstrual flux of the previous month. The next cata-

menial period had then arrived, and not venturing to express a negative opinion based merely upon the absence of this sign, I withheld the comfort which Nature brought four days tardily. The cases of pregnancy that came under observation at a sufficiently early period were then examined for this as well as other evidence indicative of such a condition, and I purpose to show the value of the sign in question as presented in the histories of the cases.

The report embraces the observations made in ten cases of pregnancy. Of these, seven had missed but one menstrual period; two had missed two; and one had missed three. It was in the first of these series of cases that I wished more particularly to ascertain the value of Jorissenne's sign. In order to attach any importance to the results obtained we must be satisfied that the women *were* pregnant. It is now ten weeks since these investigations were commenced, and the subsequent histories, which have been closely followed up, confirm the diagnoses of pregnancy made at that time. Eight of the ten women are married and have proved themselves "good breeders." Two cases afterward aborted.

The number of the radial pulsations in the minute in the different positions, for the first series, was as follows:

	Lying.	Sitting.	Standing.
Case I.....	80	80	84
Case IV.....	87	81	81
Case V.....	88	84	86
Case VI.....	60	66	70
Case VII.....	63	72	90
Case IX.....	88	94	108
Case X.....	94	76	92

In Cases IV., V., and X. the pulsations numbered less standing than in the recumbent position. In I., VI., VII., and IX. they were more standing than lying; in the first an increase of four beats, in the next of ten, in the next of seventeen, and in the next of twenty. The pulse was the same in Case IV. standing and sitting, and in Case I. sitting and lying. In Cases V. and X. it was less sitting than either lying or standing, and in Cases VI., VII., and IX. greater sitting than lying, and greater standing than sitting.

In the women who had missed two menstrual periods the records were:

	Lying.	Sitting.	Standing.
Case II.....	76	76	79
Case VIII.....	104	104	88

In one we see the pulsations were increased three beats by assuming the upright position, and in the other they were diminished sixteen by the same change. In both they numbered the same lying and sitting. The remaining Case (III.) in which pregnancy had advanced beyond the third month the pulse was 82, 84, and 86 for the corresponding positions.

Taking the ten cases we find that in five of them the pulse varied, in the different positions, from three to six beats, and in five cases from six to twenty.

These results certainly do not place Jorissenne's sign very high in our scale of valuation. The number of observations is too limited to show exactly what, if any, degree of confidence can be placed in this sign, but its fallibility is proved beyond a doubt. Moreover, the same examinations, repeated at subsequent times, gave different results. For instance, Case V. was, at the first examination, 88, 84, 86, and at another, 86, 94, 102.

These examinations were all carefully made and verified at the time by repetition. The pulse was counted by the minute, and not the fraction thereof, and in every instance sufficient time was allowed for the circulation to become settled after each change of position.

A NOTE ON THE SULPHO-CARBOLATES,
AND ESPECIALLY ON THE WANT OF UNIFORMITY IN PREPARATIONS BEARING THE SAME NAME.¹

By H. P. FARNHAM, M.D.,

NEW YORK.

It was my intention to write a general paper on the want of uniformity as to strength and quality in remedies bearing the same name; and the frequent injury to patient, and disappointment and annoyance to physician, arising therefrom. To this end I had made some notes, which in the turmoil occasioned by house alterations and repairs have been mislaid; and I shall be obliged to beg the Society to excuse a short and hurried paper. There are many articles of the *Materia Medica* which we should never prescribe without knowing where the patient will obtain the remedy, as we all know that many accidents occur from the fact that the different preparations vary so in virtue that one may prove quite inert, and another do serious injury from its unexpected strength.

My especial aim this evening will be to call your attention to the great difference in the compound salts known as the sulpho-carbolates of soda and of zinc; two remedies that some of you know I have advocated for several years as of great value in diphtheria, more especially in the earlier stages of the disease, always provided that the salts are properly prepared; and this is the essential point of this paper.

The history of the origin of these salts is well known. After the discovery of the anti-zymotic powers of the sulphites by Polli, in 1857, many experiments were made to improve upon them and unite with them the more powerful antiseptic carbolic acid, which was considered the most efficient agent known for local use, but not available for internal administration, as it was not tolerated by the stomach nor absorbed into the blood in sufficient quantity to serve any good purpose.

After many unsatisfactory trials, Dr. A. E. Sansom, of London, succeeded in producing the double salts of carbolic acid, and exhibited specimens of them before the Medical Society of London, reading a paper which was reported in *The Medical Times and Gazette*, February 22, 1868. In this paper he considered the sulphites as the most easily absorbed of our internal antiseptics, and carbolic acid the most powerful, and "that the great desideratum was a salt which should combine the two, and this desideratum he had succeeded in fulfilling in the sulpho-carbolates."

I was much interested in these contributions of Dr. Sansom and gave the new salts several thorough trials—at first always finding them disagreeable to my patient, and unsatisfactory in their results. At length considering it very probable that it might be owing to some fault in the drug itself I ordered the sulpho-carbolates from Morson's, of London, and for the past eight or ten years have prescribed no other.

Other chemists may prepare the salts as well, but these have always given me satisfaction, and I have never used any other that did not disappoint me.

In spite of the words *Morson's ONLY*, always underscored, my patients have several times been vomited and prostrated by a mixture utterly unlike that prescribed in smell, taste, and effects, and when I took the bottle on one occasion to the apothecary who had dispensed it, he excused himself by saying it was Merck's preparation, and that Merck was as good a chemist as there was in Europe.

I thought my little patient would certainly die from the prostrating effect of the nauseous dose, and sent immediately for the medicine I had ordered, which acted promptly and favorably, and would not have been recognized by any body as the same prescription.

When in London last year I called at Morson's establishment to make inquiries as to the cause of this great

difference, and was referred to the manager of their manufacturing house. I went there and was informed that their sulpho-carbolates were made precisely according to the published formula, and the only probable cause suggested for any superiority over some others was that they were always most careful to make use of the very purest carbolic acid.

Dr. Sansom gives the method of producing the sulpho-carbolates as follows:

"Sulpho-carbolic acid (*Syn.* Sulpho-phrenic acid, $C_6H_5SO_4$) is produced by the admixture in equivalent proportions of sulphuric and carbolic acids. I have obtained the pure double acid in the form of very long, colorless, finely acicular crystals, which are very deliquescent.

"The sulpho-carbolates are produced by neutralization with the various bases."

He goes on to say under the head of "*Preparation.*—I have found many specimens lacking the true characteristics of a sulpho-carbolic acid. The danger is contamination with: 1, the sulphate of the base employed; 2, the carbolic acid which evolves the odor of carbolic acid; 3, free sulphuric acid; 4, free carbolic acid. The best method is to produce, first, a definite sulpho carbolic acid by taking equivalent weights of its components, and to neutralize with the calculated weights of the oxides employed. Crystallization should take place slowly without heat.

"*Tests.*—Each sulpho-carbolic acid should possess a definite and decided crystalline form. They should give off scarcely any odor of carbolic acid; they should give no precipitate with barium chloride," etc.¹

The specimens I present differ so decidedly from each other that they can hardly be considered as belonging to the same family. Examine the *soda* salts particularly. That of Morson corresponds closely with the description quoted above from Dr. Sansom, while the other does not answer to it either in physical properties, taste, smell, chemical or remedial effects; and it seems to me that while it may be a mixture of the component parts of the double salt, it is not chemically a true sulpho-carbolic acid of soda.

To the eye Morson's salt is in the form of beautiful clear crystals; the other is an amorphous powder. The former makes a perfectly clear, the latter a muddy solution, in water. The former is a remedy that any one can take without repugnance, the latter causes disgust and sometimes terrible vomiting and prostration. In a word, one is a powerful antiseptic, that can be introduced into the economy without any disagreeable effects, while the other may have similar antiseptic properties, but with such drawbacks as render it entirely unavailable as a substitute for Morson's preparation.

STUDYING THE MUSCULAR SENSE OF DIFFERENT INDIVIDUALS.—Mr. Francis Galton has been investigating the muscular sense of various classes of individuals. He used weights, the object being to find what difference could be detected by the persons handling certain weights. These are his provisional results, subject, of course, to correction, but surprising enough for all that: 1. Intellectually able men had more discriminating power on the whole than women of a like cast of mind. 2. Men, as a rule, had a greater ability of estimating accurately than women. 3. What appears strange is that women of very sensitive natures did not seem to be more capable of distinguishing between different degrees than their more callous sisters. 4. What is stranger still is that the investigator says he found the blind, as a whole, were not peculiarly sensitive to the test, but rather the reverse. Some of the gentlemen in charge of our public institutions might profitably employ their leisure on such inquiries. The facts would be probably of unexpected importance.

Progress of Medical Science.

THE OPERATIVE TREATMENT OF PNEUMOTHORAX.—The following rules are laid down by Professor Weil, for the treatment of pneumothorax occurring in phthisical subjects: 1. Most cases of this kind offer but little encouragement for operative interference. Yet in some of even the most hopeless ones an operation may be the means of prolonging life. 2. In some cases with a relatively favorable prognosis, operative procedures may not only prolong life, but may even lead to a complete cure. 3. In the first five or six weeks after the development of pneumothorax, an operation should not be undertaken, unless the dyspnoea become so urgent as to threaten life. 4. If the dyspnoea become severe soon after the onset of the pneumothorax, and be not controllable by narcotics, then puncture of the chest-wall is necessary. If the dyspnoea speedily return, as it usually does, owing to non-closure of the opening into the lung, an incision must be made. 5. If several weeks later asphyxia threatens, it is due to an accumulation of fluid, which must be withdrawn by aspiration. Should this prove unsuccessful, then there is nothing to do but to make a free incision. 6. In cases with relatively favorable prognosis, it is advisable to operate, even though there be no danger of life. In such cases, however, it is better to wait from four to six weeks, as then the fistula in the lung will probably be closed, and the fever will also have subsided. Various procedures must be adopted, according to the character and amount of the exudation. 7. In cases where the fluid is in excess, and the air has nearly disappeared, the indication is to draw off the fluid in small quantities at a time. 8. In sero-fibrinous exudations we should draw off small quantities from time to time by simple puncture or by the aspirator. 9. If the exudation become purulent, Senator's method must be practised. 10. If a reaccumulation of pus soon take place—the conditions being otherwise favorable—incision must be practised at once. 11. If the fluid remain scanty and the air be unabsorbed at the end of five weeks or more, it would seem to be the most rational plan to let out the gas through the aspirator needle, and so bring the case under the seventh category, where the conditions for further treatment are more favorable. 12. If the case become stationary with a moderate amount of fluid and considerable gas, the withdrawal of both by the aspirator is indicated.—*Wiener Med. Wochenschr.*, No. 39, 1882.

CAFFEIN FOR HYPODERMIC USE.—The ordinary preparations of caffein are unsuitable for hypodermic use, because of their slight solubility in water. The so-called acetate and lactate of caffein are in reality not salts, but merely solutions of caffein in acetic and lactic acids. The salts formed with the inorganic acids are unstable, and not adapted for subcutaneous use. The fact that this substance exists in coffee in the form of a double salt of caffein and potassium, in combination with an acid resembling benzoic, cinnamomic, and salicylic acids, led Dr. Tanret to prepare similar combinations. He found that caffein united readily with benzoate, cinnamate, or salicylate of soda, forming a double salt readily soluble in water. The salicylate contains sixty-one per cent. of caffein, and has been injected subcutaneously without causing the slightest irritation.—*Schmidt's Jahrbücher*, No. 7, 1882.

PHENIC ACID AND IODINE IN THE TREATMENT OF TYPHOID FEVER.—Dr. Klamann (*Allgem. Med. Central-Zeitung*, No. 81, 1882) claims excellent results in the treatment of typhoid fever by carbolic acid and iodine. To avoid carbolic-acid poisoning he gives very small doses, as in the following formula: Tinct. iodi., gr. viiiss.; acid. carbol. c. glycerin, gtt. x.; alcohol, dilut., 3 iiss. From five to ten drops of this mixture are taken in coffee

or tea every hour or two. When diarrhoea is troublesome the remedy is administered in tincture of rhatany. The treatment should be begun early in the disease, in order to obtain the most favorable results.

A similar plan of treatment is recommended by Dr. Rothe (*Memorabilien*, vol. xxvii.), who reports a number of cases, in some of which the initial symptoms were very grave, but all of which resulted favorably. The formula employed by him is as follows: Acid. carbol. et alcohol., aa ℥viiss. to xv. (according to the age of the patient, the intensity of the fever, etc.); tinct. iodi., gtt. x. to xv.; aq. menth. pip., 3 iii; tinct. aconiti, ℥xv. to xxx.; syr. aurant. cort., 3 iv. Of this mixture the dose is a table-spoonful every hour; for children under ten years of age, a teaspoonful. Owing to the aconite in this mixture, however, it is difficult to determine how much of the good effect is to be attributed to the carbolic acid and iodine.

TOLERANCE BY THE UTERUS OF TRAUMATIC AND SEPTIC INFLUENCES.—Dr. Valenta relates a case in which the head of a full-term child, together with the placenta, was retained in the cavity of the uterus for six weeks. The child presented by the shoulder, and after version was delivered as far as the head. The latter resisting all efforts made to extract it, the medical attendant simply cut it off and went his way. After numerous attempts to remove it, the head was finally extracted piecemeal after remaining in the uterus for forty days. During this whole period there were no signs of reaction, the pulse and temperature remaining normal.—*Schmidt's Jahrbücher*, No. 7, 1882.

LEUCÆMIA AND PSEUDO-LEUCÆMIA.—Senator contends that the only difference between leucæmia and pseudo-leucæmia is one of degree, according to the greater or less proportion of white corpuscles in the blood. The change from one form to the other is not uncommon. In cases of chronic anæmia, with enlarged spleen, in which the number of white corpuscles is about normal, the diagnosis is pseudo-leucæmia (splenic anæmia). When, under the same conditions, the white corpuscles are increased in number, the disease is leucæmia. Senator states that leucæmia is as common in children as in adults. The question as to whether heredity or unfavorable surroundings can be regarded as etiological factors, the author is unable to decide. He denies any dependence of leucæmia upon rickets, otherwise, he says, since rachitis is so common a disease, leucæmia and pseudo-leucæmia should be met with much more frequently than is the case.—*Deutsche Medicinal-Zeitung*, No. 42, 1882.

THE PROGNOSTIC VALUE OF THE TUBERCLE BACILLUS.—Drs. Fraentzel and Balmer sum up the conclusions derived from their investigations as follows: 1. A definite prognosis in pulmonary tuberculosis may be made from the number and stage of development of the tubercle-bacilli found in the sputa. When they are numerous and well developed the prognosis is grave. 2. The number of bacilli in the sputum increases proportionately with the advance of the destructive process in the lung, and attains its maximum as the end approaches. 3. The distribution of bacilli is not the same in all cases. Sometimes they are evenly scattered about in the sputum, and sometimes are collected together in groups. 4. Their appearance is not constant. They are often small, ill-developed, and without spores. In such cases their number is always small. 5. Such bacilli are found in cases where the disease is progressing but slowly or has been checked. 6. In all rapidly advancing cases of pulmonary tuberculosis with high temperature, night-sweats, etc., the bacilli are large and rich in spores. 7. In every case in which the bacilli were plentiful there was high fever, and the converse was also true. 8. The difference in the quantity of bacilli in the fluid of a cavity and that in the lung-tissue surrounding the excavation was very

marked. In the former they were very numerous, in the latter scanty. 9. From this it appears that the sputum affords a more favorable place of growth than does the still living lung-tissue. 10. We may not ascribe the rich development of bacilli in the lung-cavity to the presence of oxygen, for they are equally abundant in the purulent secretion of a tuberculous joint.—*Berliner Klinische Wochenschrift*, November 6, 1882.

SURGICAL TREATMENT OF INTESTINAL OBSTRUCTION.—Dr. Krönlein relates several cases of obstruction of the bowels successfully relieved by operation. Where the occlusion is caused solely by obstinate constipation he recommends massage, cathartics, and enemata; but in acute obstruction he advises that no time be lost through trial of these measures, but that an operation be resorted to at once. Simple laparotomy and search for the point of obstruction is, according to Dr. Krönlein, usually unavailing, because of the marked meteorism. Lapar-enterotomy is the operation which he prefers. An incision is made in the right iliac region, and the portion of the gut which presents at the opening is seized and stitched to the abdominal wall. If the intestinal canal become permeable again the artificial anus may be closed; but, in any event, the author does not consider that life with an artificial anus is so unendurable as many are accustomed to suppose.—*Correspondenzblatt für Schweizer Aertze*, Nos. 15 and 16, 1882.

CRETEFACTION OF THE GANGLIONIC CELLS IN MYELITIS.—Dr. Friedlaender relates three cases of poliomyelitis in which a cretification of the cells of the anterior horns was observed. The author believes, on the strength of his own investigations and those of others, that calcification of the ganglionic cells is always present in acute myelitis. He thinks that the alteration of the cells in poliomyelitis is due to some infectious agent; and he is inclined to regard it as an infectious disease, a view of which many of the symptoms of the affection, he thinks, are confirmatory.—*Centralblatt für Klin. Med.*, No. 28, 1882.

PROPHYLAXIS OF TUBERCULOSIS.—Accepting the infectious nature of phthisis, Dr. Veraguth advises the following prophylactic measures: The sputa should always be disinfected. Those predisposed to tuberculosis should avoid health-resorts which are frequented by phthisical subjects. Great care should be taken to procure milk from perfectly healthy cows, both for infants and adults. Lastly, Dr. Veraguth thinks that the State should forbid the marriage of all persons suffering from phthisis or of those predisposed to the disease.—*Centralblatt für Klin. Med.*, No. 28, 1882.

INFLUENCE OF VARIOUS IRRITANTS UPON THE INTESTINAL MUSCULAR FIBRES.—From a large number of experiments undertaken to determine the influence exerted by various salts upon the smooth muscular fibres of the intestine, Dr. Nothnagel has formulated some important conclusions. He states that the effects of the potassium salts are very different from those of soda when applied locally to the wall of the intestine in living animals. After the application of a salt of potassium, a strictly local contraction ensues, while the irritation from sodium salts results in a contraction that is propagated along the intestine for some distance upward toward the pylorus. In the latter case it was often noticed that the contraction commenced several lines distant from the point of irritation, while the point itself was not affected. This never occurred when potassium was used. The contraction after sodium was slower, less marked, and of shorter duration than that from potassium. The only other salts, of a number tried, that caused a similar effect to the sodium salts, were those of ammonium. As to the question, whether these contractions arise from direct irritation of the muscles, or through some nervous influence, Nothnagel asserts that the potassium salts act directly through the muscles, but that the effect of the sodium

compounds is to be otherwise explained. In a living animal, after the mesentery has been stripped off, the reaction of the muscular coat of the intestine occurs as before. But in animals killed by breaking up the medulla, while the contraction after application of the potassium salts is unchanged, that from sodium is either entirely abolished or has lost its peculiar character. This fact, together with the peculiarities before mentioned, would seem, in the author's opinion, to point to a nervous interposition in the reaction following irritation from sodium compounds. Dr. Nothnagel is as yet unable to account for the curious fact of the ascending contractions. The experiments were made on rabbits and cats.—*Centralblatt für Klinische Medizin*, No. 29, 1882.

ACETONURIA.—Dr. Jaksch asserts that acetone is a normal constituent of the urine, and occurs as a constant product of tissue changes. In health it is found in very small amount (about one-sixth grain only, in the twenty-four hours), but in certain pathological conditions it may rise to an appreciable quantity. Acetonuria exists not only in diabetes, but is also almost constantly present in high continued fevers. The amount of acetone, usually several grains, bears a pretty constant proportion to the height of the fever. The author has never seen the excretion of acetone in appreciable amounts in apyretic conditions, except in certain cases of carcinoma, hydrophobia, and diabetes mellitus. Gerhard's chloride of iron test (a red color of the urine upon the addition of ferric chloride) does not, according to Jaksch, indicate the presence of acetone, but of acetic acid. The latter very readily, however, becomes converted into acetone under the condition of warmth and in the process of distillation. The author has occasionally observed the two substances together in the urine in diabetes, measles, scarlatina, and pneumonia. He recommends Lieben's iodoform test for the qualitative determination of the presence of acetone in the urine. From a half to one pint of urine is mixed with a moderate amount of hydrochloric acid and put into a retort. The first few drops that are distilled over are treated with caustic soda and biniodide of potassium, with the result, if acetone be present, of the formation of a cloud of iodoform. The substance is easily recognized by its odor, and further, if the fluid be made to boil, it rises with the steam and is condensed on the cool glass in crystals of six-sided plates, or six-pointed stars. When acetone is present in large amount, previous distillation is not always necessary. To estimate the quantity of acetone in a given specimen of urine, the author gives the following directions: The entire quantity of acetone in a measured amount of urine must be transformed into iodoform by the addition of sufficient caustic soda and biniodide of potassium. The resulting cloud is to be compared to that obtained in a proof solution containing a known amount of acetone, and the two deposits made of equal density by the addition of water to one or the other solution. The proportion of acetone can then be determined by the formula, $x = \frac{axv}{v'}$; x = the quantity of acetone to be determined, a = the amount of acetone in the proof solution, v = the entire volume of the fluid containing the distilled urine, v' = the entire volume of the proof solution.—*Centralblatt für Klinische Medizin*, No. 29, 1882.

INFLUENCE OF INTRABRONCHIAL PRESSURE UPON THE CIRCULATION.—Professor Sommerbrodt states, upon the strength of a number of experiments made by himself, that rapid respiratory movements, inhalation of compressed air, speaking in falsetto, or any other act which causes an increased pressure of air within the bronchi, will give rise to dilatation of the blood-vessels and acceleration of the heart's action. He explains this effect as due to a reflex loss of tone of the vasomotor system, consequent upon irritation of the pulmonary nerves. The purposes served by this arrangement are thus set forth by the author: 1. It contributes to the freer blood-

supply of the muscles. Muscular exertion causes deeper respiration, and this in turn increases the rapidity and volume of the circulation. 2. It promotes the rapid excretion of waste material through the kidneys. 3. It serves to regulate the temperature of the body by reason of the increased peripheral circulation. 4. It guards against the dangers of venous engorgement, which is the first result of intrabronchial pressure, by the compensatory arterial dilatation and increased cardiac action.—*Correspondenzblatt für Schweizer Aerzte*, No. 20, 1882.

REDUCTION OF STRANGULATED HERNIA WITHOUT OPERATION.—The following simple procedure is stated by Dr. Finkelnstein to have been successfully employed in the reduction of a large number of cases of strangulated hernia: The patient is placed in the ordinary position upon the back, and every fifteen minutes one or two tablespoonfuls of ether, mixed with a little oil, are poured upon the tightly stretched skin over the intestine. In the course of an hour the bowel usually slips back of its own accord into the abdominal cavity. This action is explained by the author in cases where the strangulation is caused by contraction at the orifice of the hernial sac, as due to relaxation of the inguinal ring from the ether. In other cases, where no contraction exists, Dr. Finkelnstein refers the favorable result to a double action of the cold in causing a diminution in size of the knuckle of intestine and in setting up forcible peristaltic movements. The oil is added to the ether, in the proportion of 20 parts to 100, simply to prevent local irritation of the skin.—*Allgem. Med. Central-Zeitung*, November 4, 1882.

CLINICAL SIGNIFICANCE OF PEPTONURIA.—Dr. Jaksch, Jr., records the results of a number of examinations made to determine the presence of peptone in the urine. In leucocythemia, although peptone was found in the blood, it was not in the urine. This fact, he thinks, to be confirmatory of Hofmeister's view, that peptone circulates in the blood in connection with the white corpuscles. The latter are not broken up, hence the peptone is not set free. Peptonuria existed in a number of cases of empyema, but as a rule only in those in which the conditions were favorable for the reabsorption of the pleural exudation. As regards the prognostic value of peptonuria, the author thinks that the excretion of peptone in the course of pneumonia, acute articular rheumatism, meningitis, etc., indicates that the inflammatory process is subsiding.—*Wiener Med. Wochenschr.*, No. 42, 1882.

INFLUENCE OF EXCISION OF THE PRIMARY INDURATION UPON THE SUBSEQUENT COURSE OF SYPHILIS.—In corroboration of the views expressed by Dr. Morrow, in a paper read recently before the New York Academy of Medicine, the following conclusions of Dr. Tomaschewski (*Wratsch*, Nos. 16 and 17, 1882), derived from observations upon upward of fifty cases, may be of interest: 1. The primary induration is to be regarded not as a local affection, but as the first objective symptom of syphilis. 2. The excision of the chancre, at whatever time it may be practised, does not protect the patients against subsequent manifestations of the disease. 3. The wound left after the removal of the induration heals usually by first intention. 4. In the majority of cases the induration does not return after excision. 5 and 6. Excision cuts short the duration of the local sore, but has no effect upon the general disease. 7. The period of incubation of the secondary symptoms is not sensibly modified. 8. The general character of the gland affections is unchanged. 9. The secondary affections of the skin and mucous membranes are influenced in no way by excision. 10. The influence of syphilis upon the general health is apparently the same. 11. The cure of the disease is not hastened. 12. Relapses, whether as regards their character, intensity, or time of occurrence are unaffected by excision of the primary indurated sore. As opposed to

these conclusions may be mentioned a communication of Dr. Saccharewitsch (*Ibid.*, No. 33, 1882). The writer states that he has performed excision of the indurated chancre in a small number of cases, with the effect of either preventing further manifestations of syphilis or materially shortening their duration. He therefore recommends the practice to be followed in all cases.

RELATION BETWEEN CERTAIN EYE DISEASES AND AFFECTIONS OF THE FEMALE GENERATIVE ORGANS.—The frequent occurrence of diseases of the eye during the progress of various disorders of the female generative apparatus has been noted by Dr. Rempoldi (*Journal de Médecine de Paris*, November 4, 1882). Among the menstrual disorders which may be accompanied by conjunctivitis, simple or phlyctenular keratitis and iritis, the author mentions especially amenorrhœa. But suppression of the menses from various causes may also be attended by affections of the choroid, by optic neuritis, retinitis, and glaucoma. In the course of inflammatory diseases of the sexual organs are frequently observed iritis and scleritis with trigeminal neuralgia. During pregnancy and lactation, Dr. Rempoldi has observed conjunctivitis and pannus. Among the diseases appearing toward the cessation of lactation, are noted corneal ulcerations, retinal hyperæsthesia, disturbances of accommodation, photophobia, and retinitis. The author includes hysteria in the list of sexual disorders, and mentions asthenopia with retinal hyperæsthesia, and ptosis with retinal anæsthesia, as having been observed at different times in hysterical subjects. Finally, he notices the ocular disturbances dependent upon the albuminuria of pregnancy, and amblyopia consecutive to uterine hemorrhages.

PATHOLOGY AND TREATMENT OF UTERINE DISPLACEMENTS.—The following practical points are set forth by Schultze, in a recent monograph upon uterine displacements: The normal condition of the uterus is one of very free movement, as can be readily demonstrated in the living subject. Changes of position that are permanent are pathological deviations. Restriction of normal movements is the characteristic sign of displacements. These consist in (1) fixation of the organ through inflammation, and (2) malposition resulting from relaxation of the ligaments. In the first class, treatment should be directed against the inflammation, in the second, the weakened ligaments should be assisted by mechanical means. Dysmenorrhœa and sterility in ante flexion and anteversion arise not from change of position, or supposed stenosis, but are due wholly to the coexisting metritis or parametritis. Treatment should be directed against the inflammation, and not against the assumed stenosis or the malposition. In retroflexion, on the contrary, mechanical treatment is indicated.—*Berliner Klin. Wochenschr.*, No. 32, 1882.

AVOIDANCE OF IODOFORM POISONING.—In a prolonged discussion on the utility and disadvantages of iodoform, at a recent meeting of the Berliner Medicinische Gesellschaft, Dr. Steinauer had occasion to make some practical suggestions. Iodoform, he stated, when applied locally was always absorbed, though very slowly, and its action was a cumulative one. Hence it was advisable to remove the dressings after five or six days, and substitute some other antiseptic agent—carbolic acid, thymol, salicylic acid, or the like. Iodoform appears in the urine in the form of iodine, in combination with an alkali. We can readily determine its presence by adding nitric acid and starch to the urine, and shaking the mixture, when the blue color appears. We have thus a simple means of estimating the amount of iodoform absorbed, and can judge whether danger of poisoning exist or not. The lethal dose in man is difficult to determine. In animals it is stated to be as follows: Guinea-pigs, thirty grains; rabbits, forty-five grains, and dogs, one drachm.—*Berliner Klin. Wochenschr.*, No. 42, 1882.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, January 6, 1883.

THE NEW VOLUME OF THE RECORD.

WITH the present issue THE MEDICAL RECORD materially increases its size and correspondingly improves its general appearance. The adoption of a larger page and a longer column will enable us in future to devote more space to communications, while the change in the general arrangement of the journal will give us even better opportunities than formerly of publishing the latest important news up to the last moment of going to press. By all these means we hope to add to the general usefulness of THE RECORD as a medical newspaper, and make it, in this respect, more acceptable than ever to our readers. Our corps of special correspondents both at home and abroad has received such additions as will guarantee us, by letter and telegraph, the latest information concerning the matters of medical interest transpiring in the different medical centres of the world. The larger amount of space at our disposal will afford us extra facilities for the prompt insertion of a greater number of communications, better opportunities for the discussion of medical subjects while they are fresh and interesting. In these respects we shall be better able to meet the more urgent demands of the journalism of the day, and to minister to the pressing needs of the active, practical, and progressive workers in our ranks. With such aims in view the character and variety of material furnished will be such as shall be most useful and instructive to the larger number of professional readers.

In this connection we are pleased to state that extraordinary pains have been taken to secure for our readers during the year a largely increased variety of practical articles. We have conceived the idea of gathering anew some of the more recent views concerning the pathology and treatment of many of the commoner diseases which are met with in general practice. Papers on these different subjects will be prepared specially for THE RECORD by many distinguished gentlemen in this and other cities. In this way we hope to compass a good part of the field of practical medicine and give to the general reader a guide for his treatment of such diseases as he meets from day to day. These articles, taken collectively, may serve to furnish him with a text-book of more than ordinary value added to the other features of THE RECORD. Many of these communications are already in hand, while the remainder, the subjects of which have been selected with especial

care, are promised when the time for their publication arrives.

We believe this to be a departure in medical journalism which will be duly appreciated by every one who desires to hear the opinions of experts in these different branches of medicine. Even if there is nothing new to most of our readers in the treatment of this or that disease, it is a comfort to know the fact and to be assured that they are working side by side with men of larger experience whose general results tally with those of the average practitioner. In any case the reader can be assured that the subjects will be presented with the view of bringing out the new and practical points connected with them. In another place the list of these subjects and their authors is announced. It is perhaps unnecessary to say in addition that everything which can be, will be done to make THE RECORD attractive and maintain its previous character as a faithful and impartial exponent of the medical opinions of the day. We simply owe this to our subscribers and it shall be our constant aim to do what we consider a plain and pleasurable duty.

COLD IN THE TREATMENT OF FEVERS.

At the recent German Medical Congress (*Verhandlungen des Congresses für Innere Medizin*, 1882) a prolonged discussion was had upon the treatment of fevers, and especially of typhoid, by the antipyretic method. Liebermeister was quite naturally the first to be heard and he stated the following propositions: In many fevers there exists in the elevated temperature an immediate danger to the patient. In such cases the problem for the physician is to overcome by suitable means this menacing condition. The foundation of all antipyretic treatment consists in the withdrawal of heat from the body, by means of cold baths. In many cases the administration of antipyretic drugs, such as quinine or salicylic acid, is also judicious. The speaker unhesitatingly admitted that there might have been some patients injured by too energetic bathing, but he contended that their number was quite insignificant in comparison with the thousands whose lives had doubtless been lost through the neglect of this mode of treatment.

He was ready to welcome any method that would accomplish the desired result, *i.e.*, the reduction of a dangerously high temperature. But he considered the treatment by cold baths to be the simplest and most efficacious means to that end. The danger of an elevated temperature lay in its long continuance. So that, if we could induce a marked remission, even if it were only for a short time, the peril was thereby greatly lessened. His own habit was to have the baths given during the night, sometimes as often as once in every hour. But in the day time he usually let the fever take its course. The patient was placed in the bath whenever his temperature rose to 104°. The speaker in concluding said that he wished to correct an erroneous impression that seemed to have arisen, namely, that he treated everything antipyretically, and only antipyretically. If there were a specific remedy for typhoid fever he would gladly employ it, but until it was discovered he should treat the symptoms as they arose.

Riess, of Berlin, thought that we should try not only to obtain remissions of the fever, but to reduce the pyrexia to the lowest possible degree throughout the entire course of the disease. A large experience had led the speaker to prefer the cool bath to the internal administration of antipyretic remedies. He used water of a temperature of about 87° , and he kept the patient lying in a sort of hammock, suspended in the bath sometimes for an entire day. Such a long immersion was seldom necessary after the first day of treatment. Afterward the patient was placed in the bath whenever the rectal temperature rose to 101° , and removed again when it had fallen to 99° . The discussion was continued by Jürgensen, Gerhardt, and others, and of course the speakers differed somewhat as to the relative merits of cold water and internal antipyretics. The general consensus of opinion, however, seemed to be to the effect that, in certain cases, the employment of the cold bath was of the highest utility, not only in shortening the duration of fevers, but also in saving life, especially where there was danger from hyperpyrexia.

We can certainly not presume to question the accuracy of these German observers, nor yet doubt the honesty of their conviction. Nevertheless we should remember that, though faithfully tried in our country, the cold-bath treatment of typhoid fever has not yielded results that have popularized this therapeutic plan with us.

Thus it would seem that we are driven to conclude that climatic or constitutional influences of a peculiarly American character prevent us from reaping the benefits which the cold bath appears to yield in other countries.

Certainly a direct abstraction of heat from an overheated body appeals to the mind as a rational method of treatment. But in the human body we are at no time dealing with purely physical problems. There can be no doubt that the chilling effect of immersing the entire body in cold water must profoundly impress the nervous system. And often, no doubt, the shock thus experienced may prove potent for evil. The steady use of the wet sheet seems, after all, a more harmless, and so perhaps equally efficacious procedure.

In this connection we are also reminded of a suggestion recently made by Dr. J. W. Stickler, of Orange, N. J. He has described a bed (see MEDICAL RECORD, April 15, 1882) which allows the patient to be put under the cooling influence of cold air, continuously applied.

This method of reducing high temperatures seems, *a priori*, a convenient and rational one. We are not aware, however, that it has ever been extensively employed. But it would certainly seem to deserve a fair trial. And perhaps it may eventually prove a good and safe substitute for the cold bath with its inherent dangers and inconveniences.

THE PARIS EPIDEMIC AND ITS LESSONS.

THE epidemic of typhoid fever has subsided in Paris, although the disease is still present, and there were quite lately over one hundred deaths per week from it alone.

The doctors of Paris have been busy of late in discussing the subject and trying to draw some conclusions that will be profitable to themselves and the world.

The epidemic, it is said, was malignant in its "morbidity," but benign as regards mortality. The disease was characterized by some peculiar features, such as the frequent development of thrush and of bed-sores, and the tendency to relapse after convalescence had set in.

In the matter of treatment it seems to be confessed that no evidence had been found to prove peculiar efficacy for antiseptics, antipyretics, or any other special methods. The statistics offered by various persons are of little value. No better results were obtained by anyone than by Dujardin-Beaumetz, who reported 87 cases with 4 deaths, under the expectant plan. M. Lancereaux, who adopted the *traitement des indications*, reported 57 cases and only 5 deaths.

The conclusion to be drawn from the Paris epidemic, as regards the therapeutics of typhoid fever, is that the disease must be watched, not actively treated. "*L'expectation armée*" was the term happily chosen as their best therapeutic guide by several who discussed the matter. We believe that the sooner this view is taken, and typhoid fever is looked upon as a disease like small-pox or scarlet fever, whose course the physician cannot greatly modify, but whose dangers we can, in part, avert, the better it will be for our science and our credit.

The matter of etiology has received much discussion from our French brethren. There has not been, heretofore, entire unanimity among them, as to the contagiousness of typhoid fever in cities. The history of the recent epidemic showed, however, that such contagiousness existed in a very mild degree. Among attendants in the hospitals, 24 caught the disease; of these 8 were patients, 11 nurses, 4 nuns, and 1 a medical student.

The origin and rapid spread of the disease are ascribed to the overcrowding of human beings, filth, and bad drainage. Some were disposed to add another factor: a peculiar modifying influence of the atmosphere. It appears to have been quite impossible to trace the spread of the disease from house to house, or family to family, or to ascribe it to any specially infected drinking-water. The vague element of "epidemicity" has, therefore, to be called upon.

THE IMMIGRANT AND SMALL-POX.

DR. JOHN H. RAUCH, in his last monthly report as Superintendent of the Immigrant Inspection Service, lays down the following propositions upon which he bases arguments for the continuation of his service:

"*First*.—The immigrant is a prime factor in the origin and continuance of small-pox in the United States—on the one hand, even if protected himself, often being the bearer of the contagion in clothing and other effects; and, on the other, if unprotected, frequently becoming a victim to the disease and propagating it to others.

"*Second*.—Local effort and expenditure, either by States or municipalities, are inadequate to the control of small-pox in any given community or commonwealth, so long as the contagion and the material for the propagation of the contagion continue to be replenished by repeated accessions of unprotected or imperfectly protected immigrants.

"*Third*.—A continuous sanitary surveillance of immigrant travel, from the port of arrival to the point of ultimate destination—such surveillance to consist of re-

peated inspections, vaccination of all unprotected, systematic observation of suspicious sickness, prompt removal and isolation of discovered small-pox or other contagious cases, disinfection of baggage, clothing, cars, etc.—is essential to supplement whatever preventive measures can be secured before embarkation, during the voyage, or at the port of arrival."

Regarding the point that the immigrant is the chief source of small-pox in the United States, considerable evidence is adduced, yet hardly enough to establish the claim that is made. Dr. Elisha Harris writes that in New York State thirty per cent. of all the outbreaks have been traceable to immigrants. The evidence from Western health officers is not so comprehensive.

In discussing his second and third propositions, Dr. Rauch criticises unnecessarily the views we have taken regarding his service. We quite concede the importance of his work and should regret to see it stopped. It appears, however, to be irrational for the United States Government to establish inland quarantine for the protection of certain districts of the country, leaving other quarantines neglected. There should be, rather, international quarantine regulations and a uniform and maritime quarantine; then, if this does not suffice, let each State take care what diseases enter its boundary. The results of depending upon surveillance after arrival and distribution of immigrants begin is shown in Dr. Rauch's own figures. Among 130,000 persons who in the past six months were added to the population of the Northwest, 23,000, or nearly one-fifth, escaped inspection in the Western District.

It seems somewhat futile to inspect four-fifths of the immigrants and leave the rest to disseminate disease as they will. We trust, therefore, that our Government will attack the evil nearer its source. At the same time we can hardly blame Dr. Rauch for being optimistic, and perhaps a little egotistic, over his own very excellent work.

A RADICAL HEALTH ORDINANCE.

THE authorities of Paterson, N. J., have had a hard struggle with contagious diseases during the past year. With regard to small-pox, especially, the efforts made for its control have been so unsuccessful as to give rise to much criticism.

An ordinance has recently been passed, however, which is evidently expected to place health matters upon a very solid basis. These new regulations provide for a most stringent compulsory notification of infectious diseases. Section I. requires every physician to report to the Board, in writing, the particulars of each case of contagious disease upon which he is in attendance; if death occur, another notice must be given by the people's very good servants—their doctors.

Similar notification of the presence of contagious disease must be given by all hotel and boarding-house keepers. School-teachers are forbidden knowingly to permit the attendance of children suffering from any contagious disease. The same prohibition is put upon parents and guardians.

The most stringent regulation, however, relates to Section VII., which reads as follows:

"It shall be the duty of the Health Inspector, imme-

diately upon report being made to the Board that any person is sick with small-pox, or any other pestilential or contagious disease which may be considered by the Board to be dangerous to the public health, to affix or cause to be affixed to the front part of the house in which such sick person may be, a sign, upon which shall be painted or printed in large distinct letters the words 'small-pox,' or such other disease, as the case may be."

The "other contagious diseases" which are to be thus advertised are: scarlet fever, diphtheria, typhus, varioloid, cholera, yellow fever, or any other disease publicly declared by the Board of Health to be dangerous.

This plan of home-advertisement of contagious disease has been tried in Chicago, if we remember correctly. It there failed, because the people did not like it, and there were constant evasions of the law. It may do better in Patterson, although we confess to being skeptical. It is not wise for the sanitarian to invade the domestic hearth too aggressively.

A NEW CITY INSANE ASYLUM.

At last our city authorities are beginning to realize that some change must be made in the care of its insane. The Board of Estimate and Apportionment have received from the City Charity Commissioners a communication asking that provision be made for the purchase of a large farm near the city upon which a new asylum can be built.

It is proposed that plain, substantial buildings be put up here, and that the chronic, able-bodied insane be transferred to them. Such a place could be made to furnish occupation, care, and shelter for one-third or more of the inmates of the City Insane Asylum on Ward's Island. It is recommended that the site be upon the water front, so as to be more accessible.

There are now over twelve hundred occupants in the Ward's Island Asylum, a number which greatly over-crowds its capacity. The project of establishing a separate asylum for chronic cases has been several times urged by us. We are glad to learn that it now promises to be adopted.

Similar provision will soon have to be made also for the chronic female insane upon Blackwell's Island.

The asylum there contains a still larger number of patients than that on Ward's Island, and the necessity for separate care and treatment of the chronic cases is very great.

BROKEN THERMOMETERS.

THE misfortunes of our correspondent, Dr. A. A. Lyon, with his thermometers, have called forth much sympathy and advice. We are in receipt of numerous letters from various readers, describing their instructive experiences and the way in which they have finally succeeded in averting the catastrophes that have so overwhelmed Dr. Lyon.

We can hardly do justice to the suggestions of all of our correspondents. And we must be especially brief with some of our enterprising instrument-makers, whose concern over broken thermometers is not, we fear, entirely free from commercial calculation.

The following embody the chief points made on the subject in hand:

Dr. W. R. Fisher, of Hoboken, recommends the use of a German silver case, with a small wad of cotton placed in either end; as a further precaution, the thermometer should be carried in the pocket-case.

Dr. T. F. Houston, of Clarkesville, Ga., Dr. Foster, of Moosup, Conn., and others, recommend the same plan, which, we believe, is a common one, and as regards the pocket-case, it is not always practical or convenient. One correspondent carries his thermometer in the upper vest pocket, the edge of which is stitched, leaving just enough space for the instrument to slip in. A rubber strap twisted about the case helps to prevent it falling out.

Dr. Charles C. F. Gay, of Buffalo, calls attention to a specially devised case manufactured by Tiemann & Co., of this city. This case contains, among other things, a place for a clinical thermometer, in which that instrument can be carried with security. Any case can be lined with flannel, however, and made more secure. It is only necessary to cut a strip of the cloth wide enough to reach half around the interior. This is covered with mucilage on one side and the end carried to the bottom of the case by the aid of a tenaculum.

Dr. Wm. R. Leonard, of this city, describes a special thermometer case made of black walnut, steamed and fashioned on a mould. It is lined with velvet, and has a padded silk top. Shepard & Dudley are the makers. Dr. Leonard has used a case of this kind for four years, and it has answered its purpose well.

The foregoing suggestions cover the matter sufficiently, and will, we doubt not, be fruitful in saving many thermometers.

A NEW ANTISEPTIC.

THE importance of possessing a powerful antiseptic which is at the same time harmless to the general system is very great.

Indeed, the discovery of such an agent is the great aim of the modern bacterial pathology. That so potent, and yet accommodating a drug, should ever be found is improbable, yet we chronicle with interest the various new claimants for the important discovery.

Somewhat over ten years ago, Mr. C. T. Kingsett, of London, began to study the antiseptic properties of peroxide of hydrogen. He reported the result of a series of experiments, to the British Medical Association, in 1876. In 1878 the antiseptic properties of this substance were rediscovered by Guttman and Fraenkel, in Germany; and quite recently the same thing was done in France, by MM. Baldy, Bert, and Regnard. The practical uses of this agent have been most demonstrated in this latter country. Under the name of *eau oxygénée*, it has been widely used in surgery. M. Pean operates in an atmosphere of the oxygenated water, instead of carbolic acid. M. Baldy employs gauze and wool soaked in the peroxide. Many French surgeons have used it as an agent for washing and dressing ulcers and abscesses. It has been very successfully used by ophthalmologists. Its value internally has not yet been demonstrated. Dr. Day, of Geelong, has given it in diabetes, gout, and rheumatism, claiming that it increases oxygenation—a view which is wholly hypothetical. Mr. Lennox Browne has used the water in nasal, throat, and aural

troubles. It has been found superior to carbolic acid as a dressing for venereal ulcers.

On the whole, the peroxide of hydrogen has been shown, thus far, to be a harmless yet powerful antiseptic. It is hardly to be claimed for it that as yet any great superiority over other antiseptics has been proved.

In a recent communication to the *British Medical Journal*, however, Mr. Kingsett announces a new preparation which he calls, unfortunately, by the apparently proprietary name of "Sanitas" oil. It is, he says, an organic peroxide, which will continually yield peroxide of hydrogen to water on being placed in contact therewith. If placed upon moist surfaces, it keeps them in an atmosphere which is claimed to be of an extremely antiseptic character. Its slow and constant action, together with the great antiseptic intensity, which many times exceeds that of the aqueous peroxide, offer, the discoverer says, peculiar advantages. Much is hoped for it as an agent for inhalation in pulmonary troubles, as well as a local application for wounds, ulcers, and the like.

OLD DISEASES WITH NEW NAMES.

THE remarks contained in the recent address of Sir James Paget, as referred to by our London correspondent, are full of sound sense and must commend themselves to the medical thinkers of the day. In this age, when only novelties are sought after, it is somewhat comforting to hear from one of the masters in the profession that their importance is more relative than positive. The old-fashioned diseases still claim our attention; the old facts connected with them still remain, interpret them as we please. The novelty is simply in the different methods by which we may explain their phenomena. We are glad to hear the distinguished orator emphasize so strongly the necessity of collecting facts for their own sake, and we admire afresh the candid spirits of the old investigators who gave themselves so contentedly and so unostentatiously to such work. The lesson of their lives cannot be too strongly enforced in this day, when only such facts are collected as may serve to explain some pet theory or bolster some absurd notion. No more striking illustration of the opposite course could be offered than the preservation of John Hunter's gummy tumor, none that could more effectually prove the folly of throwing away what we may not at the time fully understand.

FILTHY CROTON WATER.

ACCORDING to recent reports, particularly in the *Herald*, there is constantly going on more or less pollution of our water supply—hardly enough, it is true, to affect the taste of the water itself, but sufficient at least to give considerable concern to New Yorkers, and to emphasize the necessity of exercising more than ordinary vigilance in correcting the evil. At Brewsters it is said that filth of a particularly offensive character is dumped into the east branch of the Croton River, which flows through that village. For instance, on Wednesday a colored man was seen cleansing cuspidors, taken from a hotel bar-room, in this stream. On another occasion a number of fish were being cleaned in the same stream. In fact, notwithstanding an inspector has been appointed to prevent such occurrences, little or nothing has been done in that line.

SHIP-SURGEONS AND VACCINATION OF IMMIGRANTS. THE *Nautical Gazette*, quoting our editorial upon the subject, criticises ship-surgeons rather too severely. It says :

"The average ship-surgeon is a species of medical fraud, so far as the practice of medicine is concerned. He goes to sea because he could not earn his salt on shore. There are some, however, who stand high in their profession, and take great pride in having a clean passenger list. We are quite prepared to believe that 'some steamship companies buy cheap virus in large quantities and keep it until it is all used up.' Some of them would be satisfied to vaccinate their passengers with mucilage or sour flour paste for that matter, so as to save a penny. There needs to be an inspection of ship-surgeons as well as of immigrants. This we know from experience."

ELECTRICITY AS A CARDIAC STIMULANT.

A FACT of the greatest importance, practically—especially with reference to the treatment of threatening death by chloroform—has just been determined by Professor von Ziemssen. In investigating the effect of electricity upon the heart, he has discovered that the induced current has no influence whatever upon the frequency or force of the cardiac contractions, whilst the continuous or battery current most distinctly affects them. Many tracings of the movements of the heart under different conditions were first made, and a careful record was obtained of the effect of physical disturbance of the various parts of the cardiac surface. The influence of the different forms of electricity was then thoroughly investigated, cardiographic tracings being taken simultaneously. The most interesting fact determined was the complete failure of the faradic current to alter the action of the heart, or to disturb in any way its sensibility, whilst the direct battery current produced a marked effect.

THE COST OF FUNERALS.

It is claimed by one writer that one and one-fourth more money is expended annually in funerals in the United States than the Government expends for public school purposes, and that funerals cost annually more money than the combined gold and silver yield of the country in the year 1880. This does not include the cost of cemetery lots and burial-fees. While it is quite natural to properly reverence the dead, it is certainly unnecessary to make extravagant expenditures in their behalf. Many poor families cripple themselves for months in order to make a last show of respect for the departed. The carriages, flowers, and music could be used to much better advantage when the poor body was animated and could really appreciate such luxuries.

TAPPING OF THE PERICARDIUM.

DR. H. RENDU, in *L'Union Médicale*, reports that "the doubtful position and value of this operation makes the case of interest. The patient suffered from a pericarditis with effusion, produced by exposure to cold. The symptoms of pressure were severe, a puncture was made and a litre of liquid removed. A month later the patient had a double pleurisy. He finally recovered with pericardiac adhesions."

News of the Week.

THE DEATH OF GAMBETTA.

So far as can be learned the death of Gambetta must have been anticipated by his medical attendants long before hope was publicly given up. The distinguished patient had suffered for some time from diabetes. He had not taken proper care of himself, and his constitution had been sapped of its vigor. The pistol-wound in his wrist precipitated an acute illness. The symptoms described, as proved by *post mortem* examination, were those of a perityphlitic inflammation, which was followed by pyæmia, the patient succumbing finally from cardiac thrombosis. It was not thought advisable to operate, on account of his exhausted condition, death being considered inevitable.

The names of Drs. Lannelongue, Paul Bert, Charcot, and Fienzal are mentioned as attending Gambetta. This is sufficient evidence that all which was possible was done for the lamented champion of French Republicanism.

ANOTHER PROTECTIVE VIRUS.

M. PASTEUR has read a paper on *rougè*, or *mal rouge*, of pigs before the French Academy of Sciences. The disease he treats of has been very destructive in France. In the Valley of the Rhone, this year, it destroyed not less than twenty thousand pigs. Dr. Klein, in 1879, gave an account of it, and designated it *pneumo-enteritis*. Pasteur takes exception to Klein's account of the nature and characteristics of the parasite which produces the illness, holding that it has a dumb-bell shape, and bears a close resemblance to that which produces the cholera of fowls, but is less easily detected. He claims inoculation by a diluted form of the virus affords a protection. If this is true, it is a matter of importance in this country, where thousands of pigs die yearly from the disease in question.

THE NEW PRESIDENT OF THE COLLEGE OF PHYSICIANS OF PHILADELPHIA.

ON Wednesday evening of this week (January 3d), Dr. Alfred Stillé was elected President, and Dr. J. M. Da Costa, Vice-President of the College of Physicians of Philadelphia. Professor Stillé will sit in a chair that has had but eight incumbents in ninety-five years. The College of Physicians was born in 1787, and became moribund about fifteen or twenty years ago. The fact is that this institution, with an invaluable library of over twenty-three thousand volumes and a fine museum, committed the error of re-electing one president over and over again, until he died, after serving thirty-one years. This distinguished man, Professor George B. Wood, was for many years an invalid who only left his home in a carriage at rare intervals. During a considerable period the duties of the office were of necessity performed by the vice-president, who was in a similar manner perpetually his own successor. The same suicidal policy was adopted in filling most of the offices and committees.

Hence the meetings were unattended by a sufficient number of Fellows to make a quorum, except on rare occasions; not enough new Fellows were added to fill the breaches made by death; few scientific papers were read; and the occasional gilt-edged volume of Transac-

tions became a collection of obituary memoirs. The last volume, which should have been bound in black, shows for two years seven papers (79 pages), seven obituary notices (132 pages), and two committee reports.

Within the past year additional nominations for officers and committees have been made, old traditions have been trampled under foot, the Constitution and By-laws have been recast, new Fellows have been added, so many papers have been presented that some could only be read by title, the papers are promptly published in the various medical journals, the building has been altered to provide for the long-needed and surprisingly successful Directory for Nurses, the telephone and telegraph have been admitted to Fellowship, the hours for opening the library have been extended so that now it can be used in the evening, and a social or smoking-room has been established. It is also probable that in a short time an additional story will be added to the building to better accommodate the Mütter Museum.

THE DOOM OF THE BACILLUS TUBERCULOSIS.

DR. H. D. SCHMIDT publishes in the December number of the *Chicago Medical Journal and Examiner* an elaborate account of his researches regarding the bacillus tuberculosis.

Dr. Schmidt's views, as has been already announced, are that the alkaline solutions and aniline oil used in preparing the tuberculous specimens, lead to the production of minute fatty crystals. These have naturally a faint bluish tinge, which has been mistaken for staining. That the so-called bacilli, however, are not really stained at all is thought to be proved by the fact, admitted by Koch, that they lose their apparent color and disappear from sight in a few weeks. By submitting the stained sections to boiling ether, the pseudo-bacilli disappear, being, as Dr. Schmidt claims dissolved. The case against the bacilli is a strong one, and will be alluded to again. Meanwhile, it is but fair to say that other observers, after causing the bacilli to disappear by means of ether, have reproduced them by staining the sections again, showing, presumably, that the ether only washes out the coloring matter.

A POLICLINIC IN PHILADELPHIA.

MEDICAL Philadelphia has been considerably stirred of late by rumors of a new college about to be established for the clinical instruction of graduates. The name is The Philadelphia Polyclinic and College for Graduates in Medicine. It looks as though the organizers had utilized the names of both of New York's recently founded institutions, and were afraid that the metropolis would be universally recognized as *the* medical centre. The faculty of the new college is said to be composed of those well known in medical and surgical specialties, but the details have been kept very quiet. It will be an unusual circumstance in collegiate history if all the professors are of the best material. Some weak link is pretty sure to be put into every chain. Success is assured for a Graduates' College in Philadelphia if it is started with enough money and brains. It cannot be successful unless the Faculty is composed of men who are known as scientific workers

in special lines and as experienced clinical teachers. Those favorably known to the Alumni of the University of Pennsylvania and Jefferson College will therefore undoubtedly be selected. Such men as Cohen, Burnett, Levis, Mills, Wilson, Van Harlingen, Thomson, Roberts, Morton, Smith, Leffmann, and Longstreth would make a strong organization, as they are all recognized as prominent in their particular branches.

THE GOVERNOR'S MESSAGE AND STATE CHARITIES.

THE discussion of our State Charities by Governor Cleveland, in his recent Message, and the recommendations there made are disappointing and unsatisfactory. The vital questions of the supervision of lunatic asylums and the change in the commitment laws are referred to in vague terms, and the recommendations made may be interpreted as meaning anything or nothing.

The number of the insane in the asylums and poor-houses is reported to be 10,443, an increase of 384 over the previous year. The Governor naïvely says that this indicates an increase in insanity, when it really indicates chiefly an increase in population.

The other State Charities are referred to with no especial comment.

THE NEW YORK MEDICAL JOURNAL.—The *New York Medical Journal* is transformed at the commencement of this year from a monthly into a weekly periodical. It comes to us in fine dress as a double-columned royal octavo of twenty-eight pages, and is filled with well-selected and interesting articles. It opens with a lecture by William B. Carpenter on "Human Automatism," which article is followed by a series of papers on "Antisepsis in the Treatment of Wounds," by Drs. Willard Parker, H. B. Sands, R. F. Weir, J. Willston Wright, and W. T. Bull. "A Rare Case of Osteoma of the Conjunctiva" is contributed by Dr. E. G. Loring. The editorial articles are exceedingly well written, and are models of their kind. The quarterly report on Ophthalmology is made by Dr. C. S. Bull, after the style of similar ones in the monthly. The report of the Medical and Surgical Society is, as usual, quite full and accurate. Altogether, the *Journal* is a credit to medical journalism, not only of this city, but of the country. The *Journal* continues under the control of its former editor, Dr. Frank P. Foster, who brings to the discharge of his new and responsible duties every requisite qualification.

IMPROVING THE LUNACY LAWS.—The permanent commission of the Medico-Legal Society on the lunacy laws recommended, at the meeting of the society on Wednesday evening, that certificates of insanity shall be given by Commissioners in Lunacy only; that asylum patients shall have the freest communication with their friends, and have the privilege of being examined by physicians outside of the asylum every six months. It is also urged that the intermittent cases be kept apart from the chronic insane.

INSANITY AND EXPERT TESTIMONY.—Although Henry Prouse Cooper, after a long contest, has been judged sane and is now at liberty, we are confident that his will prove another Gosling case, and that Mr. Cooper himself will be demented or dead within a few years. Every

medical man of prominence, so far as we can learn, testified to his insanity.

The case illustrates again the defects both in our method of getting expert testimony, and in the laws regarding commitment. Mr. Cooper, though not a felon, was confined for several weeks in jail, and his trial cost him \$8,000.

ST. LOUIS VITAL STATISTICS.—The total number of deaths in St. Louis for the year was 7,817. This makes the annual death-rate 19.5 per 1,000, estimating the population at 400,000. The number of births during the year was 8,441.

HOSPITAL FOR CONTAGIOUS DISEASES.—The Board of Estimate and Apportionment has appropriated \$50,000 for the erection of a hospital for children suffering from contagious diseases.

FARM FOR THE CITY'S CHRONIC INSANE.—The sum of \$25,000 has been appropriated for buying a farm on which buildings are to be erected for the chronic insane now in the city asylum.

NEW YORK'S CHARITIES.—The sum of \$1,029,953 has been appropriated for the public charities of this city during 1883.

ANOTHER MEDICO-LEGAL SOCIETY.—It is reported that another Medico-Legal Society is to be organized in this city, and is to be called the New York Society of Medical Jurisprudence. As there is already one large and well-sustained medico-legal society in this city, it is not easy to understand the need of a second.

The proposed society will make the third scientific medico-legal organization in the world.

SMALL-POX IN BALTIMORE.—Small-pox is quite prevalent in some parts of Baltimore. Seventy-one deaths occurred last week. The Health Board is blamed for negligence and incapacity in the matter.

PROFESSOR AUSTIN FLINT has been in Philadelphia delivering a course of lectures to the general profession, under the auspices of the Philadelphia County Medical Society, on the "Physical Exploration of the Lungs by means of Auscultation and Percussion." The first lecture drew such an unexpected crowd that there were not accommodations for one-half the audience, and about two hundred gentlemen were unable to get into the hall. Arrangements were accordingly made to have the other lectures delivered in the very large amphitheatre of the Jefferson College Hospital, and tickets of admission were issued. The scholarly and practical character of Professor Flint's lectures will be evident when they are published. A complimentary dinner will be given to him at the Social Art Club on January 12th, the evening previous to his last lecture. It will doubtless be worthy of the distinguished physician who has honored Philadelphians by his presence among them.

THE LATE DR. HENRY ASHLAND CLAY, who was shot by his partner, Dr. Etienne Evetzky, was born in Brooklyn, N. Y., in 1851, and graduated from the College of Physicians and Surgeons in New York City, in 1876. He served at the Roosevelt, and Nursery and Child's Hospitals, and was a pupil of Dr. Wm. H. Draper, of New York. In 1879 he went to Leadville, Col., and estab-

lished a practice there; during the following year and a half he was quite successful, and made many friends by his genial demeanor, and evident knowledge of his profession. From there he went to Durango, where he continued to follow his profession, and was the pioneer physician of the town. Not very long ago he formed a partnership with Dr. Evetzky.

DEATH OF SURGEON HENRY R. SILLIMAN.—Assistant-Surgeon Henry R. Silliman, United States Army, died in Philadelphia on January 1st, in his fifty-first year.

AN OBSTETRICAL AND GYNECOLOGICAL SOCIETY has been formed in Washington, D. C.

THE BOSTON WATER SUPPLY is reported bad, and a commission has been appointed to see what can be done to secure improvement.

THE FIRST AID TO THE INJURED.—The Committee of the State Charities Aid Association for "First Aid to the Injured" has made preparations to resume the classes as organized last year.

DEATH OF DR. CORVISART OF PARIS.—A cable despatch from Paris announces the death of Dr. R. F. E. Corvisart, of that city. He had been in delicate health for the last few years. He was the author of works on phthisis and dyspepsia.

THE NEW DEPUTY CORONERS.—The coroners-elect have named as deputy-coroners: Drs. M. J. B. Messemmer, Wm. T. Jenkins, Philip E. Donlin, and Wm. A. Conway.

A NEW HOSPITAL IN YONKERS.—There is to be established, under the medical directorship of Dr. S. Waterman, of this city, a hospital connected with the Hebrew Home under the auspices of the B'nai B'rith, a society comprising New York and New England States, and having a membership of ten thousand. The grounds at Yonkers comprise nearly ten acres, and command a fine view of the river. The building thus far erected is 200 x 80 feet. The hospital will be supplied with all the appliances necessary.

The following gentlemen have been appointed to the medical and surgical staffs: Dr. S. Waterman, Medical Director; Dr. A. Jacobi, New York, Dr. S. Swift, Yonkers, N. Y., Consulting Physicians; Dr. H. B. Sands, New York, Dr. G. F. Shrady, New York, Consulting Surgeons; Dr. Hockheimer, Dr. Wallach, Dr. Meyer, and Dr. Lœwingood, Visiting Staff.

LICENSES TO PRACTISE IN ILLINOIS.—The Illinois State Board of Health has just given notice that after the current scholastic year license to practise medicine in Illinois will be granted to graduates of those schools only whose requirements include a preliminary examination on the essentials of a common school education. As but one medical school in the State conforms to this requirement, even on paper, at present, there is some stir in the various faculties as to ways and means for complying with the letter of the law.

THE LOW PRICE OF QUININE at present prevailing should be known to physicians and their patients. Quinine is selling now, according to *New Remedies*, at the rate of \$1.65 per ounce. The decline in price is due largely to the importation of German quinine.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, December 13, 1882.

GEORGE L. PEABODY, M.D., VICE-PRESIDENT, IN THE CHAIR.

DR. PEABODY presented, in behalf of a candidate, a specimen illustrating

UTERINE FIBRO-MYOMATA, WITH A CYST OF THE LEFT BROAD LIGAMENT.

DR. P. F. CHAMBERS presented a

DERMOID CYST OF THE OVARY,

accompanied by the following history: The specimen was removed by Dr. T. G. Thomas at his private hospital. The patient was thirty-four years of age, married, and the mother of two children. Up to within one month of the birth of her first child she was apparently perfectly well. At that time she began to suffer pain in the left side, which passed off a few months after the birth of her child, and recurred at about the same time previous to the birth of her second child. The second child was two years and a half old. Since that time she had complained of constant pain in the back, especially upon the left side, and, for the last year, of difficulty in walking and standing. She had also become excessively nervous. On examination a tumor was found, about the size of a turkey's egg, in the left posterior cul-de-sac, tender upon pressure, and movable. An operation was advised for its removal, and three days afterward it was performed in the usual manner. The pedicle was ligated and dropped. Antiseptic precautions were observed. The patient made a rapid recovery. The tumor contained hair, no bone or teeth. It contained but a small quantity of fluid, the soft contents, measuring about an ounce, presenting the appearance of vaseline.

DR. H. MARION SIMS presented a

DERMOID CYST OF THE OVARY,

with the following history: On November 1, 1882, Dr. Vanderveer, of Somerville, N. J., brought the patient to his office. She was fifty-two years of age, and had been married sixteen years. Up to the time of marriage her menstrual periods had always been regular, and she had enjoyed the best of health. Two years after marriage she became pregnant, and all went well up to the seventh month, when a miscarriage took place, the child being removed with instruments. It had been dead in utero apparently for some little time. This miscarriage was followed by a violent attack of peritonitis, from which she did not fully recover for two years, and at times her life was despaired of. Her menstrual periods returned with her strength and were regular until she had change of life five years ago. From that time she was perfectly well until eight months ago, when she noticed a hard "lump" growing in the left iliac region. She did not have any severe pain in it, but complained of a great deal of backache. She noticed the lump to be growing rapidly.

When Dr. Sims first saw her, he diagnosed the tumor as a multilocular ovarian cyst and advised its removal, as it was then rapidly increasing in size. The operation was performed on Saturday, November 25th, and under the carbolic spray. He was assisted by Dr. Gill Wylie, Dr. Henneberger, of the United States Navy, Dr. Vanderveer, and Dr. Payton, of Oregon. Dr. Nash administered the ether. The usual abdominal incision being made, a firm, hard cyst was exposed to view. On introducing the hand he found there were adhesions in all directions. He plunged the large trocar into the cyst, and, much to his surprise, only brought away about three quarts of a milky colored thin fluid. He then en-

larged the opening into the cyst, and on introducing his hand was much surprised to feel a quantity of soft mortar-like material. This was all pulled out and found to contain a large quantity of silky, golden hair. When fresh, the color of this substance was exactly that of oleo-margarine, and its consistency about the same. It was odorless. It was very greasy to the touch, and burned like grease when thrown into the fire. Nine pounds of this material were removed, after which he felt something more solid attached inside, about midway between the top and bottom of the sac. When this was removed it proved to be a piece of skin, resembling a human scalp, and to which was growing a beautiful blonde curl about a foot in length. On the under side of it, and encased in fat and muscle, was a molar tooth, the only one found in the tumor. Efforts were then made to enucleate the sac, and he succeeded in doing so on the sides and in front, behind the bladder. The sac was so friable that it was feared it would be torn to shreds in trying to detach its posterior adhesions, and, at Dr. Wylie's suggestion, he determined to stitch the edges of the sac to the abdominal wound, and put a Thomas' drainage-tube inside the sac, and another into the pelvic cavity at the lower angle of the abdominal incision. The wound being closed in the usual way, the patient was put into bed, and he did not dare believe she would occupy that bed much more than thirty-six hours. Much to my delight, however, she rallied well, and her temperature has never risen above $102\frac{1}{2}^{\circ}$ F., nor her pulse above 103 since the fourth day. There was no drainage from the tube in the pelvis, and it was removed on the fifth day. From the one in the sac, there is now very little discharge, but he washed it out once a day with carbolyzed warm water. On this (the nineteenth) day she is taking plenty of nourishment, her bowels are moved daily, and she says she feels very well. Her pulse and temperature are normal. Dr. G. L. Peabody had examined the skin, and made the following report:

"The epidermis, the Malpighian layer, the derma, and the subcutaneous fat layer are all present. It differs, however, from normal skin in several important respects: (a) The derma has no papillæ; (b) there is a very unusually large number of sebaceous glands in it; (c) in numerous sections examined no sweat-glands have been present; (d) certain of the hairs and hair-follicles have undergone atrophic changes, by which the epithelium has disappeared and the hair become homogeneous and translucent; (e) the fat-cells are smaller than those of the normal adult tissue."

DR. WYLIE said the case illustrated beautifully what could be done where very strong adhesions were found. It had been his fortune to see four cases in which it was impossible to remove the posterior portion of the sac, and in all the sac was drawn up tightly and stitched into the lower angle of the wound without using any ligature whatever. Then a drainage-tube was introduced and the cavity was washed out three or four times a day according to the amount of discharge. The present case differed from those referred to in the fact that so many of the adhesions had already been torn away that it was deemed advisable to put in an extra drainage-tube. One end of it was in Douglas' cul-de-sac and the other passed out at the lower angle of the abdominal incision. The peritoneal tube had been removed, but the one within the sac still remained.

DR. R. E. VAN GIESON presented a

DERMOID CYST OF THE OVARY—CANCER OF THE STOMACH,

accompanied by the following history, furnished by Dr. E. H. Wilson, House Surgeon of St. Catharine's Hospital, Brooklyn:

C. F.—, native of Germany, fifty-three years of age, married, was admitted October 19, 1882, complaining chiefly of pain in the region of the caput coli, nausea without vomiting, and general debility. Examination revealed a tumor in the right iliac fossa, ovoid in shape,

nodular at one end, about as large, apparently, as a goose-egg, not readily movable, and painful on pressure. Morphine, one-sixth grain, was given every four hours and the diet restricted to fluids.

This was the only treatment for several days, after which she began to vomit both medicine and nourishment, and the bowels became obstinately constipated. The vomiting was partially controlled by lime-water, and soon a very large spontaneous passage from the bowels followed, nearly filling the vessel. The pain continued severe, and at times lancinating, and was usually referred to the situation of the tumor. Vomiting also continued at somewhat longer intervals. The ejected matter never contained blood. The stomach finally rejected the morphine altogether, and from this time it was given hypodermically until the pain was relieved. Finally, nourishment was also almost entirely rejected. She soon began to lose flesh and strength rapidly, and died of exhaustion November 22, 1882.

Necropsy, twenty hours after death: The tumor was found to occupy the anterior fold of the broad ligament. At the point where it leaves the pelvic wall the tissues were matted together and strongly adherent. The caput coli was also adherent to the growth by old and strong adhesions. It was in no way connected with the ovary, which was normal in size and shape. The Fallopian tube was also normal in size, but bound down by adhesions and not connected with the tumor, which seemed to be of independent origin.

Further examination revealed an unexpected and entirely different morbid growth in the stomach, occupying the pylorus, involving the greater and lesser curvature, and part of the posterior wall, undoubtedly, judging from simple inspection, carcinomatous. The mesenteric glands were enlarged, and the seat of cancerous infiltration. There were no secondary deposits found in the liver.

CROUP AND DIPHTHERIA.

Dr. Van Gieson also presented a specimen illustrating the difficulty in diagnosis between so-called membranous croup and diphtheria. It was accompanied by the following history, which had been furnished him by Dr. C. Fulda, the attending physician: George K—, six and a half years of age, had been troubled with a croupy cough for some time. Dr. F. was called to see the patient first on November 29th. On examination he found a small patch of membrane on each side of the pharynx behind the tonsils. The tonsils were not enlarged, nor were the fauces inflamed. Dyspnea was not very marked; still the parents were informed of the probable danger. For the next six days there was no noticeable change in the clinical history of the case, with the exception of the disappearance of the patch of membrane on one side. There was no fever nor acceleration of the pulse. The boy was lively and cheerful, and on the sixth day he seemed to be so well that he was allowed to leave the room. On December 7th, at 6 P.M., Dr. F. was summoned to see the patient, and found him suffering from extreme dyspnea. He called Dr. Van Gieson in consultation, who performed tracheotomy at 1 A.M. on December 8th. The temperature rose to 100° F., the pulse to 160, and the respiration to 60. Quantities of bronchial secretion and purulent-looking material were discharged through the tube. On the 9th the temperature rose to 102° F., the pulse 160 to 170, the respirations 60 to 70. The patient's strength was evidently failing. No more secretion was discharged through the tube, and at 7.30 P.M. he suddenly expired. Neither before nor after the operation were there noticed any symptoms of diphtheritic toxæmia. After the operation there were some symptoms of bronchial pneumonia. Dr. Van Gieson remarked that, in this instance, the laryngeal stenosis was almost entire, and the dyspnea when tracheotomy was performed was very marked. He performed the operation as low down as possible,

hoping to get below the exudation, but he met with some difficulty on account of the prominence of the thymus gland. He believed that any person examining this child's throat at this particular stage, unless exceedingly careful, would have failed to detect any appearance of membrane.

DR. J. LEWIS SMITH thought that the history pointed to diphtheritic exudation rather than membranous croup.

DR. VAN GIESON remarked that he had seen cases where no membrane could be discovered above the glottis, but by inspection of the larynx a membranous exudation could be detected, and by questioning the parents they had given a history of having seen a membranous exudation prior to the call of the physician.

DR. SMITH remarked that doubtless such cases did occur, although they were very rare. He had one in mind at the present time, and it was one in which he watched the patient from the very inception of the disease, and there was no membrane visible, but at the autopsy the membranous exudation was found in the larynx. He believed it to be a case of diphtheria, and one of the evidences in favor of that belief was the fact that the disease also extended to other members of the family.

DR. VAN GIESON further remarked that he had seen a single case in which there was no appearance of membrane in the throat, but he ventured the diagnosis of diphtheria, and it was only twenty-four hours before death that membrane could be seen, and then only one or two patches on the posterior border of the epiglottis.

DR. GARRISH asked in what percentage of cases of tracheotomy in croup or diphtheria recovery took place.

DR. VAN GIESON replied that Dr. Fulda, the attending physician in this case, had informed him that while studying in Vienna and Berlin he found the prevailing sentiment in favor of the early performance of tracheotomy, and that the percentage of recoveries there during the past eighteen months had been somewhat more favorable than in years gone by.

DR. J. LEWIS SMITH thought that the percentage of recoveries varied in different epidemics. If the disease was of a mild type it was much greater than when of a severe type. As an average probably not more than one in five or six recovered after tracheotomy.

DR. PEABODY remarked that when a student in Vienna it was the custom in the Children's Hospital to have present at the Christmas-tree the children upon whom tracheotomy had been performed. On the particular occasion when he was present, there were seventeen children who were either then wearing tracheotomy tubes or upon whom the operation had been performed. It was the rule in the institution under the direction of Wiederhofer to operate early in all cases in which the laryngeal dyspnea was at all marked.

DR. WYETH asked what percentage of the patients were unable to attend the Christmas-tree.

DR. F. V. WHITE asked Dr. Smith whether the secondary renal trouble was common or exceptional.

DR. SMITH replied that according to his observation in all severe cases albuminuria was present.

DR. WHITE remarked that out of a large number of cases which he had seen, in only two had evidence of nephritis existed.

OSTEO-SARCOMA OF THE FEMUR—AMPUTATION OF THIGH.

DR. GEORGE F. SHRADY presented a specimen obtained by amputation of the thigh. It was accompanied by the following history: The patient was twenty-two years of age, a native of New Jersey, and had been well up to one year ago, when he injured the right knee by jumping upon a snow-plow. From this injury he was laid up for two or three weeks, then appeared as well as usual, and suffered no inconvenience from the knee until August, 1882, when the pain returned, and upon examination there was found a small swelling upon the inside of the joint just above the condyle of the femur.

He consulted a physician in his locality, who told him that it was the commencement of white-swelling, and that he would be obliged to subject himself to a long course of treatment. At that time he felt very well and deferred treatment. In the meantime the swelling began to increase and continued to increase up to the time when he was admitted to the Presbyterian Hospital, about the middle of October, 1882. Dr. Shrady then found a swelling just above the horizontal plane of the left knee and over the internal condyle of the femur. It was globular in shape and about the size of a small orange. It was circumscribed, of elastic feel, was firm in consistence, and apparently homogeneous in structure. It was deeply attached, and the overlying skin was apparently perfectly healthy. There were no enlarged superficial veins in the neighborhood, neither was there any evidence of lymphatic involvement. From the history of the case and from the situation of the tumor and other characteristics which it presented, he diagnosed osteo-sarcoma and advised amputation of the thigh. The patient went away, but returned to the hospital at the end of two or three weeks, when Dr. Shrady again examined the limb and found that the tumor had increased in size, that the pain was more pronounced, necessitating the use of morphine. A consultation was held, the diagnosis was confirmed, and amputation was advised. With the hope of saving the limb, if possible, Dr. Shrady made an exploratory incision, when it was found that the tumor was firmly attached to the bone. Before the amputation was performed, however, Dr. W. H. Porter examined microscopically sections made from the growth, and decided that it was a case of spindle-celled sarcoma. Amputation was then performed at the middle of the thigh, and at the present time the patient was doing exceedingly well. The specimen exhibited the gross appearances of periosteal sarcoma of the femur, the periosteum was separated from the bone, and at one place the growth had evidently involved the medullary cavity. The epiphyseal cartilage and adjacent tissues were also invaded. The bone at the point where the amputation was made was apparently healthy. Dr. Shrady regarded the prognosis in these cases as exceedingly unfavorable.

DR. C. C. LEE asked Dr. Shrady with reference to the general prognosis in bony sarcoma.

DR. SHRADY remarked that sarcomas connected with bone were generally of a very malignant character, particularly was this the case with the spindle-celled periosteal variety. According to Dr. S. W. Gross that special form of osteosarcoma recurred in about six-tenths of all cases in which amputation was performed, while the giant-celled sarcoma returned in one out of every twelve cases.

In answer to a question by Dr. Ridlon, he stated that there was a partial arrest of development of the affected femur, in consequence of the involvement of the epiphyseal cartilage in the disease.

PERSISTENT FORAMEN OVALE.

DR. FERGUSON presented portions of two hearts which illustrated persistent foramen ovale. One opening admitted a tube half an inch in diameter.

He also presented a specimen which illustrated a method of preparing aneurisms for museum purposes.

URETHRAL STRICTURES—RETENTION OF URINE—ASPIRATION OF THE BLADDER—MUCOUS MEMBRANE STUDDED WITH SMALL CALCULI.

Dr. Ferguson also presented the bladder and penis removed from the body of a man, forty years of age, single, and a native of the United States, who was admitted to the New York Hospital, September 24, 1881, in a very bad general condition. He gave a history of having suffered from dribbling of urine for two weeks, with lack of projectile force, ability to pass his water in only a small stream, and with frequent desire to micturate. These symptoms became aggravated, and twenty-four hours before admission he was unable to void any

urine. When examined by the house surgeon on admission, the bladder was found distended so as to reach as high as the umbilicus. The bladder was aspirated, and a large quantity of bloody urine removed. On the following morning an attempt at catheterism failed. Aspiration was again performed and ten ounces of urine removed, and the operation was repeated in the evening, when twelve ounces were withdrawn. In the course of that night the patient voided his urine voluntarily, and on the following morning it was possible to introduce a small silver catheter, which was used during the remainder of the patient's life. At the autopsy the bladder contained ten ounces of urine, the mucous membrane was hypertrophied, presented a sloughy appearance in places, and all over the surface could be seen small calculi. There were two urethral strictures, one two and one-half inches from the meatus, but not very close, and the other at the bulbo-membranous junction. About one inch anterior to the deepest stricture were two false passages.

MR. ALLCHIN, of London, asked Dr. Ferguson why he supposed that the blood in one of his specimens passed from one auricle to the other. He had seen the lesion very frequently, and supposed that it had been generally accepted that pressure of the blood in both cavities was so nearly alike that it kept the opening sufficiently closed to prevent any evidence that the blood passed from one auricle to the other.

DR. FERGUSON replied that it seemed to him the arrangement of the tissues around the opening in this instance were such that, while pressure upon one side would close the opening, pressure upon the other would open it, and that unless the pressure was exceedingly nicely adjusted the blood would probably flow from the right into the left auricle. Whether from a physiological standpoint this view would be correct he was unable to say positively, but from the general arrangement of the tissues he thought that there was no impediment to the flow of blood from one cavity to the other.

DR. WYETH remarked, with reference to the specimen of urethral stricture presented by Dr. Ferguson, that a case came under his observation recently at the polyclinic in which a stricture had existed twenty years. At one time the patient had been catheterized with a certain degree of violence, but no urine was drawn. About a week afterward the urine escaped through a fistula in the perineum. When he first saw the patient it was with very great difficulty that even a filiform bougie could be introduced into the bladder, but starting from that point he practised continuous dilatation and the patient went on and made a rapid recovery. At the present time the calibre of the urethra had been so increased in size as to admit a No. 18 without difficulty. The opening in the urethra was just behind the triangular ligament. It was interesting to know that some of these cases, at least, could be relieved by continuous dilatation.

(To be continued.)

SMALL DOSES.—The following are recommended by Dr. A. A. Smith, of New York: Castor-oil, five drops, rubbed up with sugar and given every two hours in intestinal irritation of children. Tincture of hamamelis, one drop every fifteen minutes as a sedative in children. Tincture of pulsatilla, one drop in dysmenorrhœa every fifteen minutes, also in orchitis and epididymitis. Fowler's solution, one-half drop in nausea of pregnancy and after a drunken debauch. Tartar emetic, one grain in a quart of water. Dose, one teaspoonful every fifteen minutes in the bronchitis of children. Calomel, one-fiftieth of a grain in syphilitic headache, without gummata, every fifteen minutes. Also in children with vomiting, accompanied with mucous discharges, one-half grain bichloride of mercury in a pint of water, and administered in teaspoonful doses every fifteen minutes; good for the same affections. Fluid extract of ergot, one drop every fifteen minutes in menorrhagia.—*Medical News.*

PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, December 1, 1882.

JAS. B. HUNTER, M.D., PRESIDENT, IN THE CHAIR.

A PAPER (see p. 3) was read by DR. CHARLES S. WARD, entitled

THE SIGNIFICANCE OF TEMPERATURE AFTER OVARIOTOMY, AND THE TREATMENT OF CONDITIONS, GIVING RISE TO THERMAL VARIATIONS.

The paper being open for discussion.

DR. WARD, in answer to inquiries, said that the amount of morphine used after operations varied greatly. He had had a case where eighteen minims of Magendie's solution were given at a dose and repeated within an hour. A dose of ten minims every four hours would represent about the average. The dose was regulated by the amount of pain, the number of pulsations and respirations.

DR. HUNTER said that in a case of his just recovering the respirations had fallen to five per minute.

Dr. Hunter said that he had seen the class of cases referred to by Dr. Ward, in which the fever was not at all high, and yet after death there was every evidence of peritonitis; and he could confirm Dr. Ward's statements regarding them.

DR. G. L. PEABODY suggested that these cases had their parallel in those forms of idiopathic peritonitis where there were no symptoms at all. Dr. Peabody described briefly some cases of this nature which he had seen.

DR. WARD, in response to an inquiry regarding the infrequency of shock, said that this depended upon the case and the operator. Where the operator was skilful, rapid, and unhesitating in his work, shock very rarely occurred, even if the case were a severe one. On the whole, he had not seen it very often.

DR. HUNTER had not often seen shock after ovariectomy. He referred to one class of symptoms which used to be seen, viz., those produced by carbolic acid poisoning. Now the spray is abandoned or is not brought so near the patient, and the solution is made weaker.

DR. BEVERLY ROBINSON showed a patient who was a

DEAF-MUTE WITH CONTRACTION OF UPPER AND LOWER PHARYNX, PROBABLY FOLLOWING CONGENITAL SYPHILIS.

The history of the case was as follows:

W. L. B.—came to my office on November 27, 1882, sent by Dr. E. Burke Haywood, of Raleigh, N. C., to be treated by me for chronic rhinitis.

The patient immediately informed me, by writing, that he was nineteen years old, resided in Mechanicsville, N. C., where he intended to become a farmer, and had been a deaf-mute from two years of age. He was a tall, vigorous-looking young man, and after careful outward examination presented no marks of antecedent disease, other than the scars of a glandular abscess on one side of the neck. Even in ordinary breathing, however, it was immediately noticed that inspiration and expiration through the nasal passages was noisy and obstructed, and the lips and teeth were separated most of the time. He complained not only of this obstruction in his nose, but also of water running from the eyes, of bad odor from his nose (told him by others, since he has lost his sense of smell), and of cough. He sniffled almost continually whilst writing these statements. He informed me that he had good hearing at the time of birth. When he was two years old he contracted a cold in the head, which was followed by loss of hearing. He has four brothers living, one sister, and his mother. His father died of congestive chills, and one of his brothers of inflammation of the bowels (?).

Four years ago he had a sore throat, which appeared serious for a time, but was ultimately cured by a local practitioner. He remembers having had his throat cau-

terized on several occasions during this attack with nitrate of silver. At that time and subsequently he took cold with great facility. Two years ago he began to suffer from a catarrhal affection of the nose, which had lasted without intermission ever since. Last year he noticed for the first time a fetid odor of the breath from his nose. A physician gave him a carbolic wash to correct this symptom, and he has made almost daily use of it since that time.

One day, some months ago, whilst at dinner, he felt a sharp pain in his throat, and upon examination found it was caused by a piece of bone, which was readily extracted by a physician. Later on he had a somewhat similar sensation, and was able himself to take from his mouth a piece of bone—thin, lamellar, and about half an inch square, which is, without doubt, a portion, or nearly the whole of the vomer. This piece of bone, moreover, according to the patient's statement, seemed to come down from the back of his nose. Frequently during the night, whilst lying down, yellow matter discharges from his nose. In the morning when he awakes he has a bad taste in the mouth. If he goes into the open air watery fluid runs over his cheeks from his eyes. Last summer he went to the mountains, and during his sojourn there his nose stopped discharging and his nasal affection was evidently improved. Last autumn, when he had been home a few weeks, yellow pus came again from his nose, and a red efflorescence appeared on the left outer surface of it. Upon firm pressure in this region he has an uneasy feeling, but not absolute pain. He has very considerable and constant difficulty of breathing through the nasal passages, which is increased markedly with every fresh cold. This difficulty of nasal respiration has now lasted two years, and seems almost stationary in its intensity during the past few months. Patient went to school at eight years of age, and was, at that time, quite a delicate boy. He does not remember to have suffered from "snuffles," but had a scrofulous abscess of the neck, and was occasionally unable to do much work on account of headache, dyspepsia, and colds on the chest. He never had sore eyes or any cutaneous eruption. He has had, however, at times, swelling of the bones of the lower extremities. His brothers and sister all suffer from repeated sore throats, as did his father previous to his death. One of his brothers is a mute, like himself, and possibly his condition of mutism was due originally to sore throat in early infancy.

Physical examination shows by inspection and palpation that the patient's nose is of good configuration and presents no appreciable enlargement or depression. The red blush still exists, and over this region there is decided pain on moderate pressure. Both the redness and the pain have increased somewhat within a few days. Anterior rhinoscopy shows a large, open perforation of the nasal septum, and far back in the nasal passages the probe detects a rough, unequal, resisting substance which has the aspect and quality of diseased bone, probably undergoing necrosis. Upon opening the mouth, with the light reflected into it from a laryngeal head mirror, the pharynx presents a remarkable scarred appearance, and a series of slightly elevated bands radiate as it were from the median line toward the lateral walls. The anterior pillars of the fauces are prominent; the posterior ones have disappeared, and the tonsils are so small as to be scarcely distinguishable. A small orifice is found between the free margin of the soft palate and the posterior pharyngeal wall, which makes the oral and naso-pharynx communicate with each other. This orifice is large enough to admit with slight pressure a steel sound, or guide, of about thirty-four French in calibre—on either side of this orifice, which is on the median line, the soft palate is intimately adherent to the walls of the pharynx by resisting cicatricial bands. By passing the distal extremity of the sound through this opening and carrying it to the left and right, in different directions, it was easily determined that the posterior septum of the nose had

disappeared. This manœuvre was only slightly painful. It was also noted, by forcibly depressing the back of the tongue and throwing the reflected light downward from a small laryngeal mirror, that the lower pharynx was somewhat contracted by cicatricial bands, although not to the same degree as it was in its superior portion.

An attempt was made upon the day following the first examination (November 28th) to gain a further insight into the posterior nasal passages by passing cords through the nose and exercising continuous traction upon the palate (method of Philip S. Wales). This proved ineffectual. A tupelo-tent of large diameter, but cut quite short, was then introduced into the contracted upper orifice of the pharynx, and held in place by means of twine, with a plug of lint occluding the anterior nares, in a similar manner to that followed for the arrest of profuse epistaxis. The tupelo-tent was allowed to remain *in situ* during the remainder of the day and following night.

November 29th.—It was found that the tent had not remained fixed in place, but had slipped above the contracted orifice, and found lodging in the naso-pharyngeal space. With considerable efforts of traction it was pulled through the orifice and drawn out through the mouth.

Since this date the following treatment has been adopted: Daily passage of steel sound as large as the contracted orifice would accommodate; applications of tincture of iodine and glycerine (two drachms to one ounce) to the entire interior surface of the nasal passages; the employment each morning of a carbolyzed douche of tepid water, and sniffing through the nose every night of an ointment thus composed:

R. Vaselinei.....	5 ss.
Glycerini.....	5 j.
Acid. carbolici liq.....	℥ij.

M.

Further, one granule of bichloride of mercury (one one-hundredth of a grain) has been taken four times daily, fifteen minutes after eating, together with five grains of iodide of potash, largely diluted in water.

December 12, 1882.—The patient now breathes with considerably more ease, and his nasal respiration is certainly less noisy. Crusts do not form so frequently as they did two weeks ago, and they are far less adherent. His general aspect is healthier, and the redness and soreness outside of the nose have almost disappeared. The contracted orifice, if let alone for a single day (as it was unavoidably one day), shows great tendency to contract. It is proposed in a few days to give the patient a properly adapted dilating instrument, or a series of graduated steel sounds, by means of which he shall be able himself daily to dilate the contracted pharyngeal orifice, or, at all events, to prevent it from growing smaller.

The feasibility of a surgical operation was suggested to the members of the society, and their opinion was requested in regard to it. It was looked upon by Dr. George F. Shradly and others present as *not* to be thought of for the time, or until the general constitutional condition was brought into subjection. Moreover, it was stated by some members that such operations had usually been followed by imperfect success, owing to the extreme difficulty of keeping the contracted orifice of the pharynx in a dilated condition. Sooner or later, if a wound were made, it would heal, and when it did, the likelihood was that even greater cicatricial contraction would ensue than what already existed.

The subject being open for discussion,

DR. G. F. SHRADLY said that in his opinion the patient was suffering from congenital syphilis, and was not at present in a condition for an operation, even were such advisable.

DR. SAMUEL SEXTON said that he had seen a number of cases similar to the one presented; they were, however, quite rare. They were all due to syphilis, but in all cases except one, the disease was acquired, not inherited. In this last gummata had developed in the pharynx and

produced lesions similar to those in Dr. Robinson's patient. He believed, however, that it might be found that Dr. Robinson's patient had acquired syphilis, and that the lesions had developed in the usual manner; that the deafness, if one were to be guided by the appearance of the drum-heads, had originated in otitis media catarrhalis early in life, for they were retracted and there was the usual arrest of development which arises from imperfect intra-tympanic aeration, together with the not infrequent trophic changes to be seen in such cases.

These cases had always consulted him on account of the existing deafness, and, indeed, in most of the instances the patients themselves had not been aware of the oro-pharyngeal occlusion. The deafness in these cases, which was usually very marked, occurred in two ways: one by extension of the catarrh from the pharynx, and the other by interference with the performance of the physiological functions concerned in the air-renewal of the tympanic cavity. Hence the tympanic membranes presented the appearances characteristic of chronic catarrhal inflammation of the middle ear, and were retracted by the unopposed pressure of air upon their outer surface. Then in most of these cases there is a damming-up of the nasopharyngeal secretions, giving rise to obstruction of the Eustachian tube.

As regards operations in these cases, he had made a good deal of inquiry, and had not been able to find that they did any good, the cicatricial contraction having been in all cases so great that no opening could be long maintained between the mouth and the pharynx. One of his patients had been slightly improved by the frequent use of a bougie passed from the mouth up through a minute opening (which is generally found to exist in these cases) into the vault of the pharynx, thus giving vent to secretions.

DR. C. S. WARD thought that, owing to the great tendency to contraction of all mucous surfaces, any operation in the present case for enlargement would be followed by a contraction that would eventually make the condition as bad as at first.

DR. SHRADLY said that, in suitable cases for operation, much benefit might result from small multiple incisions into the cicatricial bands, and the subsequent dilatation of the parts by bougies.

DR. C. L. DANA read a paper (see p. 6) entitled the

ABSORPTION OF NUTRIENT ENEMATA.

In the discussion DR. ROBINSON related the case of a small child suffering from intussusception, which he had seen with Dr. Cleveland. The patient was suspended head downward and water was injected into the rectum. Suddenly there was a gush of water from the child's mouth and the obstruction disappeared. The child died twenty-four hours later. He had wondered whether it was possible that the injection went the whole length of the canal. He had at first been incredulous, but subsequently was led to believe that it was possible.¹

THE RESULTS OF KOCH'S DISCOVERIES, writes Dr. Formad (*Phila. Med. Times*), are now a matter of important consideration. In Germany, by imperial order, in military hospitals phthisical patients are separated from other cases as carefully as small-pox patients; so a gentleman tells me who has just come from Germany. Even here the community begins to regard the disease as eminently contagious. I know of an instance of a young woman suffering from phthisis being locked up and avoided, perhaps neglected, by the members of her own family, for fear of the contagium. I have learned of several consumptives who have become worse from the mortification of having their friends avoid them, some even going so far as not to shake hands with them. The moral effects must certainly be most deleterious to these unfortunate creatures and to those who surround them.

Correspondence.

LONDON LETTER.

(From our Special Correspondent.)

THE DEATH OF SIR THOMAS WATSON—SIR JAMES PAGET'S ORATION—OLD DISEASES AND NEW NAMES—FACTS AGAINST THEORIES.

LONDON, December 23, 1882.

THE Nestor of British Medicine, as he has often been termed, has passed from among us. As you already know, he died quietly on the evening of Monday, December 11, at his son's residence at Reigate. No other than a fatal termination to his illness could indeed have been expected from the first, considering his advanced age. He doubtless foresaw this clearly himself, as, when first attacked, his remark was that it was "the beginning of the end." His good constitution enabled him to struggle against his malady for some time, though suffering much pain. He was interred on the Friday following his death in the parish churchyard at Reigate. Numerous members of the profession attended his funeral, including the President of the College of Surgeons, Mr. Spencer Wells, and the Registrar of the College of Physicians, Dr. Pitman, and all the medical attendants of the deceased in his last illness, viz., Drs. Walters, George Johnson, Greenhow, and Holman, and Mr. Lister.

His son, who succeeds him in the baronetcy, is not a medical man.

Born in Devonshire, in 1792, and educated at Bury St. Edmund's Grammar School and St. John's College, Cambridge (whence he graduated as tenth wrangler), he only began the study of medicine at the age of twenty-seven. He entered St. Bartholomew's Hospital, where he studied under Abernethy, afterward studied at Edinburgh, and finally graduated at Cambridge (1825). He married and started in practice in Henrietta Street, in which street he lived till his death, though not in the same house. He was elected a Fellow of the College of Physicians in 1826, and Physician to the Middlesex Hospital. He was Professor of Clinical Medicine for two years at University College, and of Forensic Medicine for five years at King's College. He is, perhaps, best known to the world as the author of the classic "Lectures on the Principles and Practice of Medicine," which he delivered there, as Professor of Medicine, from 1836 to 1840.

He was made a baronet in 1866, and was president of the College of Physicians for five years, dating from 1862. He attended the late Prince Consort, was Physician Extraordinary to the Queen, and took charge of Sir Walter Scott on his last voyage from London to Edinburgh.

Sir Thomas, although unprepossessing in appearance, was genial in manner, upright in conduct, and a sound and skilful practitioner. He had at one time a large private practice. It is, however, nearly thirty years now since he began to retire. At that period he announced that he would not in future visit patients, but he continued to see patients at his house for several years, a privilege of which many availed themselves.

It is related of a Northampton physician—the late Dr. Robinson, I believe—that, wishful to retire, he removed to a house a mile from the town and charged two guineas instead of one, as before, a procedure which instead of lessening doubled his practice.

Sir Thomas' last public appearance was at the College of Physicians at the installation of Sir W. Jenner as president, when, as the senior Fellow present, he took part in the ceremony. He wrote at intervals in the medical periodicals till within a short time of his death. He admired Abernethy, whom he said he had heard Lawrence once term the only genius in surgery he had ever seen. Liston consulted him in his last illness. It is worth mentioning that in Sir Thomas' last illness, when suffering from bladder trouble, he specially requested that Mr. Lister might see him, and under Mr.

Lister's treatment the local trouble improved. His faith in the antiseptic treatment was thus evidently strong, and shows that though retired from active practice he interested himself in the literature of the profession to the last.

A recent event of interest has been the delivery of the first "Bradshawe Lecture" at the College of Surgeons, by Sir James Paget, Bart. The oratorical powers of "the golden-mouthed Chrysostom of the profession" (as he was recently termed by Sir W. Jenner at the banquet to the Army Medical Officers engaged in the Egyptian expedition) are well known, and a large audience assembled on the 13th. About four hundred members of the profession were present. Most of the leading men were in attendance, but Sir W. Jenner was conspicuous by his absence. Every seat was occupied, and several distinguished members of the profession had to stand. The lecture occupied an hour and concluded precisely at four.

An ex-president of the college, who sat near me, remarked: "There he is—exact to the minute—I can't think how he does it." Sir James, although not possessing by any means a powerful voice, speaks very distinctly, so that every word was easily heard, and he made few references to his notes. Taking for his subject "Some Rare and New Diseases," he remarked that some diseases were not really new but old, although only differentiated in modern times. As an instance he mentioned typhoid fever, the exact nature of which was only determined by Stewart and Jenner, both of whom are living, but John Hunter put up a specimen showing a typhoid ulcer of the intestine which is still in the College Museum. The disease was therefore existent though not recognized. A specimen of a syphilitic gumma in a muscle was also prepared and preserved by John Hunter, a lesson, Sir James Paget remarked, to all of us not to throw away what we do not understand. On the other hand, we had some almost certainly new diseases, viz., osteitis deformans and Charcot's disease of the joints. The lecturer remarked that these diseases might be produced by a process of development from other diseases—possibly by the blending of the characters of two or three diseases. He urged that we should study diseases as Darwin studied. Patient observation was necessary.

Unusual specimens of disease should not be neglected. It was erroneous to say "the exception proves the rule." It should be rather for surgeons to say "the exception proves the rule." As the Scripture says, "Prove all things."

Accuracy in diagnosis should be aimed at. Drugs were often blamed and thrown aside as untrustworthy when the fault really lay in ourselves—in our diagnosis. The value formerly ascribed to mercury in many internal affections was alluded to—the fact being, that since the visceral lesions of syphilis have been studied many of these affections have been shown to be syphilitic, and the action of mercury in many of these cases was thus explained.

ORIGIN OF CYSTS IN THE KIDNEY.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: My attention has been drawn to a communication made by Dr. Heitzmann at the New York Pathological Society, of the researches of his pupil, Dr. Jeannette B. Green, on this subject, published in your journal for October 21, 1882, p. 470. To quote from your report, Dr. Green says, "The way in which cysts are formed is as follows: first, the interstitial as well as the epithelial tissue of the tubules breaks down with inflammatory or medullary corpuscles, and thus an embryonal tissue is produced, sometimes occupying large territories of both the cortical and pyramidal substance. Next a transformation of the medullary into myxomatous tissue takes place, marked by the presence of a light, nearly homogeneous basis substance, which is traversed by nucleated,

bioplasyon strings. In further growth these delicate strings perish, and a cavity is formed filled with an albuminous liquid."

In the "Transactions of the Pathological Society of London for 1880," you will find a paper by me on the "History of Granular Kidney," from which I quote the following: "Another mode in which the destruction of tubules is completed is shown in Fig. 8, which represents a comparatively early stage of the process. The drawing shows cross sections of several convoluted tubules filled with round cells, which are not so closely packed as in Fig. 6. The sections vary very much in diameter, some of the tubules being evidently dilated. In some there are very few cells, in others none, the whole lumen being filled with a hyaline material, staining very feebly with carmine. These appearances, which may be very readily seen, were first described by M. Simon more than thirty years ago, as 'cystic degeneration of the kidney,' but have not received due attention. *They are, in fact, due to the formation of a myxomatous or gelatinous tissue from the young cells filling the lumen, by which the basement membrane is distended, and a cyst is formed.*"

Again, under the changes in the Malpighian bodies, I say, "The cellular mass has become converted into a delicate gelatinous tissue containing stellate elements. Still later the contents may be quite hyaline and stain feebly with carmine, forming a little mucous or colloid cyst, the whole process being quite analogous to that which I have described in the tubules, with this exception, that these Malpighian bodies are not enlarged, or, at least, to any notable degree."

The same descriptions are to be found in my paper in the "Transactions of the International Medical Congress, for 1881," of which I enclose you a copy.

I am glad to find that my statements have received this valuable confirmation, and am much obliged to you for allowing this opportunity of directing attention to them, as, although published in widely circulated Transactions, they appear not to have been known to Dr. Heitzmann or his pupil.

I am, yours faithfully,

ROBERT SAUNDY, M.D.

47 NEW HALLS, BIRMINGHAM, ENGLAND, December 5, 1882.

HOOKS FOR THE

EXTRACTION OF FOREIGN BODIES FROM THE EYE, EAR, AND NOSE.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR: While reading Dr. A. H. Buck's instructive case of removal of a locust bean from the ear canal by partial detachment of the auricle, in THE MEDICAL RECORD of December 16, 1882 (p. 676), and Dr. S. Sexton's remarks on the same subject in THE MEDICAL RECORD of December 23, 1882 (p. 721), I thought I might say a few words on the usefulness of a small blunt hook, the concave side of which is roughened and hollowed out. This little instrument has rendered me good service on so many occasions that I always have it in my ordinary pocket-case. I demonstrated it to the American Ophthalmological Society in 1873 ("Transactions," 1873, p. 108), mentioning its advantages in extracting foreign bodies from the interior of the eye. It is of flexible silver, so as to be curved according to necessity, yet of sufficient strength to exert a greater traction than seems required for the extraction of any foreign body from the cavities mentioned above. Every one who has had some experience in the removal of foreign bodies from the interior of the eye knows how unavailable in general toothed forceps are; they almost invariably slip off, unless the foreign body be embedded in soft tissue, such as the iris, with which they can be extracted in common. The numerous ingenious kinds of canula forceps which were constructed twenty and thirty years ago, have, as far as I

am informed, almost completely got out of use. Better are the roughened anatomical forceps, which, offering a larger surface of contact, have a firmer grasp and hold on the foreign body. In most cases it is, however, still surer to pass a blunt hook behind the body and draw it toward the opening in the corneo-scleral capsule.

The same holds good for the ear and nose. Hooks have been employed in affections of these organs for many years, and are recommended in every text-book. They are easily introduced, as in almost all cases there is a chink somewhere between the foreign body and the walls of the canal. Malgaigne,¹ who considers them to be the most appropriate instruments for extracting foreign bodies from the ear, points out that in children the ear canal is broadest horizontally, in adults vertically. N. Rau² says that the best of the numerous instruments is a hair-needle curved at its closed end, as Deleau³ recommends.

This, as all kinds of curette or spoon-like instruments, will, I think, do very well when the foreign body is near the external orifice of the canal, so that the curved end can be passed around it. For those situated deeper, a hook which can be introduced on the flat, and during its advancement pressed against the canal, appears more serviceable. When behind the foreign body it is turned so that the curved portion grasps the body from behind. A blunt hook, such as is recommended by Lister and others, and with which also Dr. Buck succeeded in his above-mentioned case, is, however, more likely to slip off than one whose concave side is roughened and hollowed out. This condition I have found of advantage in seizing angular or smooth bodies which are quite likely to escape an instrument with rounded and even surfaces, but are firmly held by one which is provided with a roughened groove. Though the modification appears insignificant, it bears on a practical point which in certain cases may determine the success of the operation.

Experience makes us skilled in the use of different instruments, and I do not doubt that soft bodies may be extracted with Dr. Sexton's or other toothed forceps. In dealing with hard bodies I would never attempt the use of any kind of forceps, for the probability of pushing them deeper into the canal is almost a certainty. The verdict of the profession in this regard is nearly universal. The case of Dr. Joy, which Dr. Sexton quotes in support of the use of his forceps, is by no means a felicitous one, as I have convinced myself by reading the original publication in *The American Journal of Otolaryngology*, vol. iii., p. 144. The locust bean had lain in the ear canal surrounded by pus and granulation tissue for over two months—time enough to soften as much as possible. "The patient was etherized, and several small pieces of the shell and of the fruit were removed with Dr. Sexton's new forceps. The boy disappeared from observation for five months. There was a free discharge of pus, and several polypoid growths obstructed the canal. These were removed by the snare, and all but a small portion of the bean was removed by the forceps, the fragments coming away piecemeal in thin, rather tough sections. The case is still under observation, and the remaining portion will probably soon pass out of the canal without surgical interference." So far the report of this case, which produces an entirely different impression from what one receives by the woodcut in Dr. Sexton's letter, where the whole bean is beautifully in the grasp of the instrument.

As to the removal of foreign bodies from the ear in general, I do not remember a single case in which I failed by syringing or the hook. My experience, as that of any one man, is, of course, limited. I may fail in my endeavor to-morrow. If the grooved hook prove insuffi-

¹ Gazette des Hôpitaux, No. 58, 1841.

² Lehrbuch der Ohrenheilkunde, p. 374, 1856.

³ Mémoire sur les Corps étrangers dans le Conduit auditif. Gaz. Méd. de Paris, p. 161, 1823.

cient, I would not be in a hurry, but have a hook constructed that could be introduced straight, having an end-piece which, when beyond the foreign body, would by means of an articulation and a stem divide into two small prongs directed at right angles to the stem, and applying themselves firmly to the posterior surface of the foreign body, say a glass bead. I would make the end-piece of this instrument thin, so as to pass easily through a narrow fissure between the foreign body and the wall of the canal. The surfaces touching the foreign body may be slightly concave and roughened. Such an instrument with one blade has, however, been recommended by Leroy d'Etiolles.¹ A hook with two prongs, which are closed while being introduced but open by pressure when behind the foreign body, can be constructed in different ways—for instance, according to the pattern of Liebreich's or Matthieu's iris forceps.

Delay in removing a foreign body from the ear is only exceptionally connected with any danger. Certain substances which swell by imbibition may produce inflammation and prevent the secretion from escaping. Politzer says,² "the enlargement from syringing with water may be prevented by immediately pouring alcohol into the ear." Not only in that case, but in every other when a swelling foreign body produces inflammatory intumescence of the walls of the meatus, nay, even in perforations of the membrana tympani and in purulent otitis media, is alcohol an excellent remedy for relieving all those symptoms, as nobody knows better than Politzer himself. Absolute alcohol poured into the ear several times daily will absorb the water from the swollen foreign body as well as from the inflamed tissues around it, make both of them shrink, and thus create free space and facilitate the removal of the intruder.

H. KNAPP, M.D.

December 24, 1882.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In my article, "A Case of Foreign Body in the External Auditory Canal," published in THE MEDICAL RECORD of December 16th, I drew certain conclusions which, as will be seen by the subjoined extract of a letter, reflected unjustly upon the physician who first saw the case. I am now convinced that my remarks upon this physician's interference were not well founded, and in simple justice to a professional brother, may I ask you to publish this brief communication.

ALBERT H. BUCK, M.D.

(Extract from letter.)

"I may say that no effort was made by me to remove the bean, but instruments were used simply to dilate the opening in order to see the bean, if possible, and to get an idea of its position. The first instrument used by myself was an Anel's probe; with this I discovered that there certainly was something in the ear, about an inch from the external meatus, and got the impression that it was firmly lodged. I at no time saw the bean. The first instrument used was a hair-pin, in the hands of a nurse or one of the lady guests at the house, who thought to remove it without alarming the mother. The next instrument used was a crochet-needle, in the hands of one of the gentlemen guests. The only instrument used by me with the idea of getting the bean, or that touched it, besides the probe spoken of, was one borrowed from a dentist, and very similar to the one shown in your article; but as the boy cried the moment the bean was touched, and as some of the beans had been placed in water for some time and found not to swell, it was thought a few hours' delay would do no harm, and the mother was advised by me to go to the city. . . . I am positive that the bean was impacted when I first saw the boy, and that I did not move it in the slightest degree."

Army News.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from December 23, 1882, to December 30, 1882.

PERIN, GLOVER, Lieutenant-Colonel and Surgeon. Granted leave of absence for one month from December 19th. S. O. 217, Department of Dakota, December 20, 1882.

BILL, JOSEPH H., Major and Surgeon. Will report to the Commanding Officer Fort Omaha, Neb., for duty. S. O. 134, par. 4, Department of the Platte, December 21, 1882.

KILBOURNE, H. S., Captain and Assistant-Surgeon. Granted leave of absence for one month, with permission to apply through Headquarters Military Division of the Missouri for an extension of two months. S. O. 218, Department of Dakota, December 21, 1882.

REED, WALTER, Captain and Assistant-Surgeon. Relieved from duty as Attending Surgeon Headquarters Department of the Platte, and will report in person to the Commanding Officer Fort Omaha, Neb., for duty. S. O. 134, Department of the Platte, December 21, 1882.

TURRILL, H. S., Captain and Assistant-Surgeon. Upon being relieved from duty at Fort Omaha, Neb., will proceed to Fort Fred. Steele, Wyo., and report to the Commanding Officer of that post for duty thereat. S. O. 134, par. 5, Department of the Platte, December 21, 1882.

HOPKINS, WILLIAM E., Assistant-Surgeon. Granted leave of absence for two months, to commence January 1, 1883, with permission to apply for an extension of two months. S. O. 88, par. 1, Military Division of the Atlantic, December 28, 1882.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Comparative statement of cases of contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending December 30, 1882.

THE BACILLUS TUBERCULOSIS NOT A FAT CRYSTAL.—Dr. J. O. Hirschfelder, Professor of Clinical Medicine, Cooper Medical College, San Francisco, sends us the following very interesting letter: "In No. 23, Vol. xxii. of THE RECORD I find a statement of investigations of Dr. H. D. Schmidt, of New Orleans, proving the bacillus tuberculosis of Koch to be simply a fat-crystal. If this assertion were true it would cast a shadow of doubt upon all the bacteriological work done within the past few years. I have confirmed the investigations of Koch upon the sputa of a large number of cases under my charge, finding the bacillus in every case of phthisis in my wards during the last three months, besides many in private practice. I have employed Ehrlich's method, and have experienced no difficulty in demonstrating the organism. In order to test the statement of Dr. Schmidt, I

first prepared a specimen of sputum by Ehrlich's method, finding numerous bacilli; I then placed the preparation in ether and again examined it, no bacilli were visible. The natural inference was not that the bacilli were dissolved, but that the color was washed out by the ether. The preparation was therefore restained like a fresh specimen and the bacilli were found as before. I likewise prepared two covers by spreading sputum upon one of them, breaking it up as well as possible, placing a second thin cover upon the first, and drawing the two rapidly apart so that the covers should be as nearly alike as possible. One cover was then stained in the ordinary way, the other was placed in boiling ether, in which it remained for about twenty minutes, and was then washed thoroughly with fresh ether, so that no fat should remain. This specimen was then stained by Ehrlich's method, and the two covers were compared. I found and readily demonstrated to the medical gentlemen present not only that the bacilli were not dissolved by the ether, but that, on the contrary, they stood out more plainly in the specimens treated with ether on account of the washing out of the fat-granules which otherwise slightly obscure the field."

AN AGGRIEVED CORRESPONDENT, of Rochester, N. Y., writes us as follows: "In THE MEDICAL RECORD of the 16th inst., p. 690, you did an injustice in quoting the Physio-Medical College, of Cincinnati, O., as being an eclectic institution, which is false; it has never been recognized by the Eclectic Society."

THE WAYNEFLETE CHAIR OF PHYSIOLOGY AT OXFORD.—The Waynflete Chair of Physiology has been filled by the election of Dr. J. Burdon Sanderson, F.R.S., who will henceforth regularly deliver lectures on Animal Physiology and Histology to members of the University. The endowment of the Chair is mainly derived out of funds set apart for the purpose from the income of Magdalen College, the emoluments of two Fellowships forming the principal stipend.

DR. HERMAN BOSKOWITZ died December 26th, at his home, in Brooklyn, N. Y., after a long illness. Dr. Boskowitz was a remarkable looking man in appearance, being little more than a dwarf in stature. For forty years he enjoyed an extensive practice. Before the war he was an active abolitionist, enjoying the personal friendship of Horace Greeley and other distinguished republicans. Early in his career Dr. Boskowitz earned a great reputation by curing one of the Clydes, of the great ship building firm, of blindness. Dr. Boskowitz, who was seventy years of age, was a native of Vienna, but came to this country when very young.

THE SUBJECT OF WOUND-DRESSING, the old time-honored subject of debate among surgeons, still crops up from time to time. At one time water-dressings were in favor; then came carbolic oil, antiseptic gauze, tow, etc. The senior surgeon at one of the large London medical schools always applies a poultice to his stumps the day following amputation, and with very excellent results. The weathercock of professional favor is now veering round to infrequent dressing with some dry absorbent material, and absolute rest. Pressure is also steadily gaining ground. The two latest contributions on the subject of wound-dressing are those of Dr. Edward Thomson on puff ball, and Dr. Lockhart Gibson on salicylic silk. A surgeon of large hospital experience told me the other day, in the course of conversation, that recently he had, after amputation, always tightly bandaged over the stump a large sponge which had been dipped in carbolic oil and wrung out till nearly dry. This he left on for a fortnight or more, with very excellent results.—*Cor. of American Practitioner.*

OZONE AND THE BLOOD.—Professor Binz some time ago announced that ozone, when inhaled cautiously, had a hypnotic effect. He has recently made further re-

searches regarding the effect of ozone on the blood. It has usually been asserted that ozone introduced into the blood had a tendency to injure it by forming methaemoglobin. Binz finds that ozone passed through blood does not have very much effect any way.

THE ELECTRICAL SOCIETY is the name of a new organization recently started in Chicago.

"MINERAL" ORGANISMS.—During the past year, the French chemists, D. Monnier and C. Vogt, presented, through M. Robin, to the French Academy of Sciences the results of some experiments, showing that the forms peculiar to plants and animals also appear under certain circumstances in purely inorganic things. Dr. H. D. Valin has repeated these experiments (*Chicago Medical Journal and Examiner*) and made the following observations: In a flask full of soluble glass were placed fragments of sulphate of iron, ten grains in weight, which immediately began to assume a colloid condition on the outside, and shot tubular prolongations, colloidal and cellular, which grew at the rate of half an inch in twenty-four hours. Some attained to two inches in length, and were about one twelfth of an inch in diameter. All these prolongations shot a number of slender filaments from various points of their surface, and these attained a length of a few inches in a few hours. After some days or weeks, all these organisms assumed a crystalline condition, and become empty inside. Some of them rose to the surface of the liquid. They were insoluble in water; they remained intact when exposed to air, and when introduced in a newly prepared flask at the same time with fresh fragments, they hastened the metamorphosis of these. The addition of water to the soluble glass rendered the experiments more easy, and saved time.

SECONDARY HEMORRHAGES AND THEIR CAUSE.—Dr. Charles C. F. Gay communicates a valuable paper on this subject to the *Buffalo Medical and Surgical Journal*. Dr. Gay is inclined to doubt the accepted views regarding the cause of secondary hemorrhage. He says:

"The tendency of the blood-current is, I believe, at first to pass through arterial anastomoses rather than toward the capillaries. In 'St. Bartholomew's Hospital Reports' I find the following experiment, reported by William Harrison Cripps. He says: 'If water be injected into the common iliac artery of a rabbit it will circulate through the capillaries, returning by the vein. If the external iliac and the superficial femoral be now tied, the water will still return by the vein, only much more slowly. If the femoral artery be now divided below the ligature and water still injected by the common iliac, it will be found that a greater quantity of the water will return through the cut (lower) end of the femoral than by the iliac vein.' This experiment shows, at least in the case of the rabbit, that even with the iliac vein open, less resistance is afforded by the anastomoses of the arteries than is afforded by the capillaries. This writer has collected fifty-three cases from various sources and classified them according to the plan of treatment. The result of treatment is thus shown:

	Died.	Recovered.
Ligation of external iliac.....	12	2
Amputation.....	2	3
Re-opening wound.....	7	5
Pressure and bandaging.....	3	12
No treatment.....	4	0
Total.....		50

The percentage of recoveries, as here shown, is greatly in favor of suppressing hemorrhage by pressure and bandaging, the method recommended by Dr. Gay. Religation, being found unnecessary to control hemorrhage, constitutes in itself, I think, a partial concession to the theory that the hemorrhage is venous in these cases, and not arterial; or, if not venous, then arterial from rupture of a branch of the anastomotic system of vessels, from which the blood derives its scarlet hue."

A QUININE JOURNAL.—*The Monthly Review of Medicine and Pharmacy* will hereafter take the name of *The Quinologist*. The New York medical man is reputed to be a good deal that sort of thing.

PERI-UTERINE CELLULITIS WITH ABSCESS POINTING IN MIDDLE LINE.—Dr. Frank W. Thomas of Marion, O., sends us the history of a case of a woman aged thirty-seven, who at her sixth confinement was delivered of a dead foetus sixteen days after the first beginning of labor pains. Three weeks later the patient was attacked with phlegmasia alba dolens; this disappeared in about four weeks, and then there developed symptoms of a pelvic cellulitis, the whole abdominal surface becoming hardened. For three months the patient suffered greatly from pain in the lumbar region and pelvic organs; morphine was resorted to and used continuously for months. The patient suffered from the chronic cellulitis for over a year. In about the fifteenth month the abscess pointed at a place about midway between the pubes and umbilicus. It was opened and two quarts of pus escaped. The patient then rapidly recovered. Our correspondent, who treated the case in the last months, very pertinently asks whether pointing could have been brought about sooner.

POLICLINIC OR POLYCLINIC.—The word polyclinic is derived from *πολις*, a town, and *κλινη*, a bed. It means, therefore, and always has, since its introduction as a word, a city clinic or hospital. A frequent mode of spelling the word in American medical literature is polyclinic. This assumes, arbitrarily and incorrectly, that the word is composed of *πολυς*, many, and *κλινη*.

THE FREQUENCY OF AND DANGER FROM NARROW PELVES.—Dr. W. Fishel read a paper before the German Medical Society of Prague, in which he stated that the usual estimates of the frequency of narrow pelvis in Germany were too high. These estimates made the proportion vary between 14 and 20 per cent. Hecker, of Munich, found the per cent. to be only 1.5; Müller, in Berne, 16; Goenner, in Basel, 7; Winckel, in Dresden, 3; Fishel, in Prague, 15.6. In Breisky's clinic, at Prague, the mortality in these cases was only 1.5 per cent.

TINCTURA IODOFORMI COMPOSITA.—Under this title, Dr. G. Beck describes in his "Therapeutical Almanac, 1880-81," a very useful formula for a solution of iodoform and iodide of potassium, which can not only be taken internally (three times a day, fifteen drops in sugared water), but is in place in all cases where the iodine treatment seems to be adapted for external application, and is capable of causing a radical disappearance of tumors of various kinds, as also of inflamed glands, etc. The original formula—iodoform, 1 part; potassii iodid., 70 parts; glycerin, 70 parts; spir. vini rect., 100 parts—is pharmaceutically incorrect, because the iodoform is not completely dissolved in this solution. The following modification is recommended, which, while not lessening any of its effects, represents a complete solution, to which Balsam of Peru is added as a corrigens to the iodoform:

R. Iodoform	8 grms.
Balsam Peru	3 "
Solv. in spir. vin. rect.	20 "
Solutioni admisc.	
Kalii iodid.	70 "
Ft. solut. in aque dest.,	
Glycerin pur	āā 35 "
Filter.	

DOCTOR AND DRUGGIST—A SINGULAR LITIGATION.—Not long since, a physician in this city who had invested money in a retail drug store was obliged, by the failure of its proprietor, to take the stock as "collateral" for his investment and sell it to some one else. After the bargain had been completed, so we are informed, he said that he would be very glad to send the purchaser what

prescription business he could. Whether our information is correct or not as to the foregoing details we cannot say, but the purchaser of the store lately brought suit in the Court of Common Pleas, for the recovery of \$5,000, as damages for an alleged breach of contract. The complainant states that the doctor promised to send him all his prescriptions to be filled, but, in fact, he has never sent him any prescriptions at all. The doctor demurred to the complaint on the ground that the contract, if made, was void, as impossible of performance, and immoral. On November 20th, Judge J. F. Daly handed down a decision on the demurrer, in which he holds that the contract is such as may support an action, and that the demurrer must be overruled. Judge Daly says that there is nothing improper in a physician contracting to advise his patient to go with his prescriptions to a particular drug shop. In action for damages, for a breach of such a contract, there might be much difficulty in getting the necessary evidence, but that fact did not furnish any reason why the action could not be maintained.

THE PATHOGENESIS OF SECONDARY TUMORS.—We have received from Dr. Henry Wile a pamphlet upon the above subject and embodying the results of the author's elaborate researches. Dr. Wile furnishes strong evidence in favor of the view that secondary tumors are developed by metastasis and not by virtue of any dyscrasia. He states in a note that prior to Dr. M. T. Prudden he discovered that adult cartilage when transplanted may continue to grow.

PHTHISIS CONVEYED FROM DOGS TO MAN.—Dr. E. G. Janeway relates a number of cases of phthisis (*Archives of Medicine*) illustrating its possible contagiousness. Among others was the case of a phthisical young man who kept a pet dog. He was accustomed to sleep with the dog nestling in his arms. The animal became affected with a cough and subsequently died. Another dog shared the same fate: a third dog suffered from a cough, but its owner died of phthisis and the dog subsequently recovered.

DR. POLK'S REMARKS BEFORE THE ACADEMY OF MEDICINE.—Dr. W. M. Polk wishes to make the following corrections in the report of his remarks before the Academy of Medicine, December 21st:

In first paragraph, for "supposed difficulties in the performance of either the Cæsarean section or Porro-Müller's operation," read "Thomas's operation for Cæsarean section."

In the next paragraph, the last two sentences should read: "With regard to the difficulties in performing Thomas's operation, he referred to the remarks of Dr. Harris, of Philadelphia, one of the ablest advocates of Cæsarean section, who spoke of Thomas's operation as one that was difficult and scientific, requiring extraordinary anatomical skill. Dr. Polk, however, had reached the conclusion that it was a very easy operation to perform when placed in contrast with Cæsarean section, or any of its modifications."

THE THERAPEUTIC GAZETTE occupies a unique and useful place among medical journals. It deservedly congratulates itself upon the successful closing of its sixth year.

THE PACIFIC MEDICAL COLLEGE has recently been incorporated under the name of the "Cooper Medical College." This change is the result of a munificent gift by Dr. L. C. Lane to the college. This gift is a new building valued at \$100,000. The school was asked by Dr. Lane to be called the Cooper Medical College, after Dr. E. S. Cooper, one of the fathers of medical education on the Western Coast. Dr. Lane's action is a most generous one in every way.

We are glad to learn that the new school has adopted an obligatory three-years' course.

The Medical Record

GROWTHS IN THE NASAL PASSAGES.¹

By F. H. BOSWORTH, M.D.,

PROFESSOR OF DISEASES OF THE THROAT IN THE BELLEVUE HOSPITAL MEDICAL COLLEGE, NEW YORK.

It is not my intention this evening to go over the whole subject of neoplasms in the nasal passages, but simply to ask your attention to some of the commoner forms of growths, met with in every day practice, and to bring before you some suggestions in the way of treatment. By the nasal passages, it should be understood, is meant the whole of the nasal air-tract, extending from the nostrils in front to the border of the soft palate posteriorly. This tract being from a physiological point of view a single channel for the passage of the inspired air, whatever the anatomical boundaries may be. By far the most common of all growths occurring in this tract is the so-called

ADENOID OF THE VAULT OF THE PHARYNX.

I think it is a somewhat general impression that this affection is a rare and obscure one, and moreover, that it gives rise to a train of symptoms peculiar to itself. The point of view to which I ask your attention to-night is rather that the disease is an exceedingly common one, and that it is one of the various, and perhaps the most frequent of the morbid conditions which give rise to an abnormal discharge from the nose, and hence is obscured and lost sight of under that very vague and indefinite term "nasal catarrh." Nasal catarrh is an exceedingly meaningless term. In former years, when our means of diagnosis were imperfect, and our methods of exploring the nasal passages were very crude, it is not to be wondered at that all diseases which give rise to a discharge from the nasal cavities were grouped under this general designation. Of late years our means of diagnosis have been so far perfected that it is possible in every case, unless possibly in very young infants, to bring under ocular inspection the whole of the lining membrane of the upper air-passages from the nostril to the trachea. I say every case, and I think the assertion a perfectly safe one, for even the most irritable throat, by the exercise of a little patience and deftness, will easily be so far brought under control as to admit of a satisfactory rhinoscopic examination. This thorough examination, then, will reveal to us in a very large majority of cases, some definite morbid condition, to account for the "catarrh," the removal of which will be followed by a radical cure of the disease. Among the common conditions which may cause a catarrhal discharge may be mentioned rhinitis hypertrophica, rhinitis atrophica, nasal polypus, deviated septum, syphilitic ulceration or necrosis, strumous ulceration, the presence of foreign bodies, adenoid of the pharynx, etc.

Chronic catarrhal inflammation of the mucous membrane lining the nasal passages develops in two varieties, the hypertrophic and the atrophic form. Hypertrophy, involving the mucous membrane of the nasal cavities proper, has been well designated rhinitis hypertrophica. The same hypertrophic process developing in the vault of the pharynx has been called adenoid of the pharynx. Nature has been very lavish in her endowment of the upper air-passages with numerous glands and follicles,

whose function is to pour out upon the mucous membrane an abundant mucus, by which it is kept in a soft, moist, and pliable condition, otherwise, the constant passing to and fro of the inspired air, often dry and irritating, would tend to rob it of its moisture and cause a dryness by which its proper functions would be seriously impaired. These glands and follicles manifest a tendency to aggregate themselves together in various localities. The most notable instance of this is between the pillars of the fauces, constituting what is called the faucial tonsils. Quite a large group of glands is found at the pharyngeal vault. Wherever we find these masses of glands, we find them manifesting a tendency to become the seat of chronic inflammatory changes. These changes in the pharyngeal vault always result in hypertrophy. I have never met with a case of atrophy. A description of the normal glandular structures, which exist in this region need not be entered upon. They were first fully described by Luschka, and hence the mass is often spoken of as Luschka's tonsil. The condition to which I invite your attention consists in the development in this region of more or less well marked, distinctly outlined growths, which vary from the size of a coffee grain to that of a large chestnut, or even larger. Loewenberg and Meyer describe these as consisting of adenoid or true glandular tissue, while Woakes considers them to possess certain features of the papillomata, and gives them the name of *adeno-papilloma*. In this view I believe he is quite alone. Their true nature is, undoubtedly, adenoid. They consist in a true hypertrophy of the normal glandular structures which are found in this region.

The following description has been furnished me by Dr. Heitzmann, of this city, who has very kindly made microscopic examinations of a number of these tumors which I removed.

Microscopical examination of the pharyngeal tonsil.—Five growths of the pharyngeal tumor were handed to Dr. Heitzmann by myself. He examined them after they were hardened in chromic acid and embedded in a mixture of paraffin and wax.

On transverse section a number of features are observed, common to all the five growths. These are:

First, they are covered by a layer of columnar ciliated epithelia which exhibits the features of stratified columnar epithelium. The single columnar epithelia greatly vary in height, and exhibit sometimes long, sometimes short, bent cilia. Between the elongated feet of the epithelia irregular corpuscles of varying shape are visible, such as occur throughout the mucous layer of the aerial passages, the larynx, the trachea, and the bronchi. Only in one specimen was one side of the tumor covered by a narrow layer of stratified epithelia, probably corresponding to the medial aspect of the tumor, without cilia, with a gradual transition into columnar epithelia.

Second, all the tumors exhibit a lobate appearance, the fissure between the lobes being sometimes shallow and at other times very deep, dividing the whole mass into a number of longitudinal ridges. Each ridge may again exhibit a varying number of shallow papillary protrusions. Under the microscope correspondingly we observe large protrusions, which are caused by the follicular formation of the tissue, and small ridges of a papillary aspect caused by narrow protrusions of the subjacent tissue.

Third, the main mass of the tumors is composed of lymph tissue, formerly termed adenoid tissue, from the

¹Read before the New York Academy of Medicine, January 4, 1883.

mistaken idea that this tissue is glandular in nature. No epithelial formations enter, however, the structure of the tumor, save the depressions and furrows between the lobes, sometimes penetrating very deeply into the mass of the tissue, and there producing manifold secondary convolutions. Beneath the epithelial cover there is no fibrous connective tissue around the lobes, while the papillary elevations are produced by a delicate fibrous connective tissue freely supplied with lymph corpuscles.

According to the general structure of lymph follicles and lymph ganglia, we find in the tumors under consideration a varying number of lymph follicles, consisting of an accumulation of lymph corpuscles, and supplied with a comparatively small number of blood-vessels. The follicles are separated from each other and enclosed by what is known as interfollicular strings. In these both a myxomatous reticulum and the fibrous variety of the connective tissue is more developed than in the follicles, and the blood-vessels are somewhat more numerous. Only in one of the specimens was there a marked fibrous interfollicular tissue with comparatively few lymph corpuscles. In all others the fibrous connective-tissue was but little developed, which feature would account for the comparative softness of these new formations.

With high power of the microscope in all specimens the features common to lymph tissue are discernible. There is a myxomatous reticulum ill-defined and crowded with lymph corpuscles in the meshes within the follicles. There is a more developed myxomatous or fibrous reticulum with comparatively less lymph corpuscles in its meshes within the interfollicular strings.

In one case a cyst was observed in the tissue near the surface, just perceptible to the naked eye, the size of a small pin's head. This cyst is lined on one side by flattened epithelia, on which even ciliae are still recognizable, while the opposite side lacks an epithelial cover, but is composed of lymph corpuscles in connection with a delicate myxomatous tissue, filling in part the cyst. This latter feature indicates that the cyst has not arisen simply from an obstruction of an interlobular fissure, but is due to a transformation of the epithelial cover, at least on one side, into a medullary, and from this into a myxomatous tissue.

The examination proves the formations under consideration are no tumors, in the proper sense of the word, but a hyperplasia of the lymph tissue, which constitutes the so-called pharyngeal tonsil. A difference between hyperplastic faucial tonsils and pharyngeal tonsils is that in the former the fibrous connective tissue is, as a rule, far more developed than in the latter.

This explains the fact I have noticed in operating with the snare, that the faucial tonsil is cut with the extremest difficulty, while the latter are severed with the greatest ease, offering but trifling resistance to the wire.

As a matter of course, formations of a simple hyperplastic nature are benign. This is in accordance with the clinical fact that their extirpation, in the great majority of cases, is not followed by recurrence. The lymph tissue is, however, the sample of a malignant type of tumor proper, the so-called lympho-sarcoma, or lympho-myeloma. Should, by a continuous growth, the lymph tissue keep increasing, no doubt it will establish a malignant tumor, such as has been observed by several writers in this region.

During the past eighteen months I have met with 75 cases of adenoid disease of the pharyngeal vault. Of these there were:

Under the age of 10.....	5
Between the ages of 10 and 15.....	16
“ “ 15 “ 20.....	27
“ “ 20 “ 30.....	23
“ “ 30 “ 40.....	2
“ “ 40 “ 50.....	1
Above the age of 50.....	1

Of these 49 were females and 26 males. We thus see

that the larger number occur about the age of puberty, it being very rare in small children, and also in adults beyond the age of thirty. The deduction from this is quite obvious, viz.: that the growths gradually shrink and disappear with the development which sets in at puberty. We thus find a very striking analogy between this affection and hypertrophy of the faucial tonsil, not only as regards its normal histology and pathology, but also in its development and clinical aspects.

In a large proportion of the cases which I have seen it occurs as a separate and independent affection, less than one-half showing any morbid condition in other portions of the nasal passages. The most frequent condition with which it is associated is rhinitis hypertrophica or chronic inflammation of the mucous membrane lining the nasal cavities proper. In ten cases it was associated with enlargement of the faucial tonsils. In four cases it was met with in connection with rhinitis atrophica or dry catarrh, three of these having reached the stage of *ozæna*. The cause of these growths lies simply in the tendency toward hypertrophy as the result of inflammatory changes which characterizes the lining membrane of the upper air tract and its appendages, under the stimulus of repeated colds. I do not believe it ever to be a manifestation of a systemic dyscrasia, but rather that it is purely a local disorder. It occurs in children more frequently than in adults, for the same reason, that all glandular structures in childhood are more prone to take on morbid changes.

This *diagnosis* is usually quite easy. Meyer and Loewenberg both insist on a digital exploration in addition to the use of the rhinoscopic mirror. This I have often done, but have never found it absolutely essential. The introduction of a finger, forcibly as it needs must be, behind the palate of a child very naturally excites pain, often retching, and always terror and apprehension, and it seems to me much better to retain the confidence of the child by resorting to simpler measures when all that can be desired is accomplished by such. In all cases, even in children of seven or eight years of age, with the exercise of a little patience, I have succeeded in obtaining a thorough inspection of the pharyngeal vault, by this means gaining, I think, a fairer estimate of the size, shape, and location of the growth than can be gained by digital exploration. I should say, however, that as a rule, it is important to make use of sunlight or the calcium light in making the examination, as the ordinary gas-jet is not sufficient to thoroughly illuminate the cavity of the pharynx, especially if a small mirror is used.

Symptoms.—The prominent and most troublesome symptom to which the presence of these growths gives rise is an excessive discharge of mucus or muco-pus; indeed, nearly all the cases which have come under my care have come for nasal catarrh. The source of the discharge is, undoubtedly, in the hypertrophied glands themselves, their normal secretory function not being destroyed by the morbid process, which has given rise to the hypertrophy, but is, on the contrary, greatly increased. We find them, therefore, pouring out large quantities of mucus or muco-pus, which in the larger proportion of cases makes its way into the lower pharynx. In those cases in which the growth has attained a large size, the discharge makes its way through the nasal cavities proper, and is voided through the nostrils.

Voice.—Another symptom which may be traced directly to the existence of these growths, and perhaps the first to be noticed will be the altered character of the voice. This is changed into what Meyer calls the dead voice. It is the voice of one with a cold in the head, that is the nasal twang is more or less completely abolished. In this way “m” and “n” become “eb” and “ed.” In order to give rise to this, the growth need not be large. It may occlude but a small portion of the posterior nares. If you will glance at the diagram, you will see that in order that the voice shall have its full nasal resonance, the vault of the pharynx should be quite clear. If but a small growth projects from its wall it seriously interferes with the sound-

waves, which in nasal sounds should have a clear field from the vocal cord to the roof of the nares. If they impinge upon the slight projecting shoulder of a growth located in the pharyngeal vault they are to an extent smothered, and the whole tone of the voice deadened.

The manner in which the singing voice is affected by these growths in the pharyngeal vault offers many points of great interest. Nature is very lavish in her endowment of the various organs of the body by which their different functions are performed, and so supplies an organ capable of doing vastly more work than it is usually called upon to perform. The larynx when called upon for an ordinary voice responds readily, and will supply apparently a clear, healthy, conversational voice for years, even when there may exist very marked morbid change. Let the voice be taxed by a prolonged and labored effort, as in a sermon or address, and the weakness soon makes itself felt. I have little doubt that many in this room to-night, who are not called upon to make any especial use of the voice, and who are conscious of no noticeable weakness, were they called upon to take pastoral charge of one of our city pulpits, would at the end of the season find it necessary to seek a six months' vacation in Europe at the hands of their congregation for a clergyman's sore throat. The singing voice taxes the very highest powers and capabilities of the larynx, and demands not only a healthy larynx, but a healthy condition of the whole upper air-tract. The recognition of this latter truth I believe to be of the utmost importance. The vocal waves are set in motion by the vibration of the vocal cords, the pitch of the tone is regulated by the tension of the cords, and here in the main, the function of the larynx ceases, unless we add perhaps quantity or loudness of voice. These qualities of the voice which we call timbre, its character and resonance, are given it by the pharyngeal and nasal cavities. These should be entirely clear of any obstructing morbid condition or changes in their lining.

In the lower or chest register, so called, the nasal and pharyngeal cavities are of comparatively little importance. The voice depends largely on the larynx. In the middle register a healthy pharynx is of importance, but in the head register a healthy nasal and pharyngeal cavity are absolutely essential. The manner in which the singing voice soon breaks down under the action of a pharyngeal growth is quite simple. As soon as a note in the upper register is attempted, the singer is conscious of something wanting, the tone is muffled, from the fact that the vocal waves striking upon the mass are suppressed as it were, the sounding-board function of the pharynx is destroyed. The singer, therefore, in order to overcome this obstacle, attempts, though generally without success, to increase the power or volume of the voice. The larynx is taxed beyond its strength, and ruptured capillaries or ruptured muscular fibres result, and a chronic laryngitis is the consequence. It is much as if the rector of Grace Church should attempt to make himself heard by a church full of people with a feather mattress fastened into the sounding-board over his pulpit.

It is a very noticeable fact with singers that it is the head register which becomes first impaired in a failing voice, and in many cases it is the head register alone which is weak, the middle and chest notes being taken with ease and in clear voice. This illustrates the truth of what I have for a long time urged in my teaching. The nasal passages are the first to become the seat of catarrhal disease, and the tendency is very marked for this to extend downward, and furthermore, that in the very large majority of instances, so-called chronic laryngitis is but a secondary condition, resulting from disease in the nasal cavities, the laryngitis being a symptom, as it were, of the disease in the parts above.

The effect of the growths on the sense of hearing has been long recognized. In eight of the cases which I have seen, the impairment of hearing was quite marked. In a larger number of others the impaired hearing was

not complained of, but was determined by the ordinary watch test, twenty of the cases presenting ear symptoms. In two of the cases there had been severe attacks of otitis media, while in six there had been complaint of frequent attacks of earache.

I scarcely feel justified in saying much of this feature of the disease, from a lack of familiarity with ear diseases, yet in making a very large number of rhinoscopic examinations I have necessarily inspected the Eustachian orifices and observed the functions and muscular movements of that region.

Impaired hearing from the presence of adenoid growths in the pharyngeal vault has been attributed to pressure on the Eustachian orifice. These growths are of a soft, pulpy consistency, while the eminences which surround the Eustachian orifice are hard and dense; hence, any pressure exerted upon them by an adenoid growth would have but slight, if any effect. I think a far more plausible explanation of the symptoms is in the interference with renewal of air in the middle chamber caused by their presence in the pharynx. Any cause which interferes with free nasal respiration, if continued sufficiently long, is liable to cause impaired hearing, by its interference with this function. The method in which this occurs, I take it, is that nasal stenosis, arresting the to-and-fro current through the nasal passages, causes a stagnation in the pharyngeal vault, and necessarily a certain amount of rarefaction of air in that region. Moreover, the free action of the levator palati muscles is interfered with by the presence of these growths, and this movement is of the utmost importance in accomplishing this mechanism of air renewal. In studying these parts by the rhinoscope, the impression is gained that the tendency of muscular movement here is to force air into the middle ear. The constant and almost ceaseless impulse of sound-waves upon the tympanum must necessarily cause a rarefaction of air in the middle ear, and this loss is compensated for by the mechanism above alluded to.

That the ear symptoms are due to an extension of catarrhal inflammation to the Eustachian tube, I think is very questionable. I am disposed to think this is an extremely rare occurrence. Certainly it is very rare to find the lining membrane of the Eustachian orifice in a condition of catarrhal inflammation. In one case which has been under treatment, there was very distressing tinnitus aurium. In this case the adenoid pressed upon the Eustachian orifice; the symptom was very markedly relieved by the removal of the growth, though not entirely removed. In this case there was no impairment of hearing.

Nasal stenosis is quite a prominent symptom of this affection, and is present in cases where the growth has not attained an unusual size. This may not be so noticeable during waking hours, but during sleep, when the voluntary muscles of respiration are not brought into play, it is more prominent, and the patient sleeps with mouth open. The vicious effect of this I need not enter upon at full. Habitual mouth-breathing, especially during sleep, I believe to be a most prolific source of throat catarrh, and liability to bronchial disorders.

It is a very noticeable fact that these growths show noticeable change in size when examined at different periods, which would indicate simply that under the influence of damp weather or other causes, they are liable to become the seat of an active turgescence or distention of their blood-vessels, by which their size is temporarily increased.

This occurrence, especially in children, is attended with an increase of secretion, with obstruction to nasal breathing.

Cough is present in certain cases, especially if there is much secretion, which has made its way down the pharynx into the larynx, exciting a laryngitis. The cough, again, may be the result of the habitual mouth-breathing.

In one case which came under my care about a month

ago, a young lady of twenty, the only symptom was a persistent hoarse, dry, barky cough. The only morbid condition discoverable in lung- or air-passages was a small adenoid. This I removed with almost immediate relief, and since then the cough has gradually disappeared.

In this case the cough was undoubtedly of a reflex origin, something in the nature of the ear-cough which we occasionally meet with, due to an accumulation of cerumen in the outer ear, or some other aural irritation.

Treatment.—This consists in their total extirpation. The only question that arises is as to the best method of its accomplishment. Chemical agents, chromic acid especially, have been recommended by several writers on the subject. I have tried this method and find it to be utterly unsatisfactory. The cutting forceps, as recommended by Cohen, of Philadelphia, Woakes, of London, and others, I have never used, but it always seemed to me a somewhat formidable instrument, difficult of nice manipulation, and moreover harsh and painful. The curette recommended by Mackenzie I formerly used with considerable satisfaction, but it did not seem adapted for use with the larger growths.

Meyer, of Copenhagen, Michael and Hartmann, of Berlin, recommend the use of cutting instruments introduced through the nares and manipulated by means of the finger passed behind the palate. Meyer's instrument consists of a stout ring with an inner cutting edge, the whole mounted on a stout rod. The other instruments mentioned are of a similar construction. Meyer furthermore advises, after the removal of the growth, that the remaining fragments be separated by a curved instrument with a rasp surface, which is passed around the palate and the base of the growth rasped as it were. Finally he advises the cauterization of the denuded surface. These procedures I can only refer to without comment other than that they seem somewhat unnecessarily severe. I have never made use of them.

Voltolini, of Breslau, Michel, of Cologne, and Loewenberg, of Paris, give preference to the galvano-cautery. There are two methods in which this may be used—first, the removal by the burning through the base with a heated wire, and second, the destruction of the growth by means of an incandescent button-electrode.

The first method I do not regard as feasible, although Michel claims success in it.

As regards the absolute destruction of these growths, or in fact any morbid growths of any size by the galvano-cautery, I have only this to say. It is an immensely overestimated instrument, and, in my experience, has utterly failed to accomplish what we formerly anticipated from it.

If we apply a cold electrode to a tumor and then close the circuit, the loss of heat is so great that, as a rule, a more than very dull heat is not obtained, the result is but a very superficial charring of the mass. In the vault of the pharynx this procedure only is applicable, as a rule, for it would require very nice manipulation to pass a heated electrode to the point desired without touching healthy portions of the passages. Still, if this were done, and an electrode were used in which the heat were developed before entering, there is yet but a very superficial destruction accomplished, and the ablation of even a small tumor by this means becomes a tedious process, occupying weeks and months, requiring an interval between each application for the exfoliation of the slough, and this may be attended by the unpleasant accompaniment of an offensive discharge. Moreover, I believe we should always recognize the fact that the application of the galvano-cautery is attended oftentimes with a very severe reaction, setting up renewed inflammatory processes, by which the tumor may be stimulated to new development, and a part at least of what has been accomplished may be counterbalanced by the renewed process of growth.

There remains only to describe a very simple method,

which I have practised exclusively in the last year, and which, it seems to me, possesses marked advantages over any other device. This consists in the use of a modification of Jarvis' snare *écraseur*, which I show (Fig. 1). As will be

seen, I have had constructed an ordinary snare with a distal tube of six in-

ches length: the end of this is curved in a quadrant of a circle whose radius is one and one-fourth inch. This is now mounted with a No. 5 piano-wire, which I regard as by far the most useful number, as combining elasticity, strength, and resistance. Having observed the growth and carefully estimated its size, a loop is formed which will embrace it, and is then bent forward over the end of the instrument, in order to give it a decided kink. The wire is now played out of the snare about an eighth of an inch, and the whole loop is now thrown backward toward the handle of the instrument, giving it another bend. As will be seen, it is in a position for easy introduction behind the palate, without touching the part, and may be passed immediately to the base of the growth. The palate of course is now immediately retracted by reflex irritation, but only embraces the tube of the snare, without in any degree hampering the manipulation.

The instrument is now held firmly in place, while the loop is rapidly drawn in by turning the screw. The action of the bends in the wire loop is now perceived. As the wire is drawn in the loop is thrown backward with considerable vigor, and embraces and severs the growth. In this manner even a broadly sessile growth is easily seized and extirpated. There is but trivial hemorrhage, but little pain or retching, and the whole manipulation is accomplished very easily, simply, and speedily. After the withdrawal of the instrument, the tumor is expelled through the nose by blowing. Occasionally it drops into the pharynx below, but this is very rare. In no case has any patient experienced the slightest annoyance from the growth dropping too far down in the air-passage, nor do I regard this as an accident that is liable to happen. The operation by this method has never required an anæsthetic.

In three cases of children, in whom the control of the faucial movements prevented the manipulation, I was compelled to give an anæsthetic and resort to another method, which may be described in a few words. In these cases the growth was severed by passing an ordinary straight snare through the nose. Having mounted the snare with the wire, the loop was bent sharply down over the end of the instrument, giving it a kink, and then drawn within the tube until a loop only remained sufficiently small to pass through the nares; this was passed vertically until the loop was in the pharynx, when the instrument was turned, bringing the loop into a horizontal position, with the side undermost toward which the larger loop had been bent. The wire was now played into the pharynx, when the bend which had already been given it threw the loop downward, nearly to a right angle. The whole instrument was now pressed firmly against the pharynx, which, as will be seen, threw the loop over the growth. Holding the instrument firmly pressed against the pharynx, the screw was rapidly turned

Fig. 1.

and the growth severed. As soon as the instrument was withdrawn the child's head was drawn over the table with the face downward, and the trifling hemorrhage allowed to go on until the child could be aroused, when the tumor was expelled by blowing the nose.

In this manner, as a rule, the whole growth may be removed, but in the first-described manipulation portions may be left. This is easily ascertained by examination as well as their location, and the manipulation repeated. This may be done a number of times at one sitting, entailing but little annoyance or weariness to the patient. As regards recurrence, I have never in any of my cases seen any such tendency. Perhaps it is too early to hazard an opinion, but certainly I think it safe to assume that the method of operating described, if thoroughly done, leaves a far less liability to recurrence than the use of forceps, caustics, or the galvano-cautery. The inflammatory reaction after these methods is certainly very notable. In the use of the snare, whether in adenoid or other growths, I have never in any single case noticed the slightest reaction occur, with the sole exception of some few cases where I removed tonsils by it.

This question of reaction after removal of growths I regard as one of exceeding importance, and desire to lay especial stress on the fact of its absence after operations by the snare.

The next variety of growth in the nasal passages to which I will call your attention is

NASAL POLYPI.

Nasal polypus means properly a tumor of the nasal cavity attached to the parts beneath by a narrow pedicle. As a matter of clinical observation, the only pedunculated tumor with which we meet in this region is the myxoma. A more exact classification would demand that to each variety of growth the name should be given which describes its pathological character. In this way we would do away with that very careless classification which describes nasal polypi as well as nasopharyngeal polypi. I have never met with a case of polypus in the naso-pharynx; the growth which is described under this heading being usually a fibroma, which is always a sessile tumor.

Nasal polypus has been recognized since the days of Hippocrates, and consists in the development in the nasal cavities of soft, rounded, jelly-like tumors, resembling as much as anything the pulp of a grape. They generally occur in both cavities, though occasionally are found in but one. When they are confined to one cavity, it is my observation that they have been present but a short time and are few in number. From this I would infer that they commence in one cavity, and that their presence there very soon leads to their development in the other.

A single polypus is a very great rarity, as they seem to develop in clusters.

During the past year there were treated at my clinic for diseases of the throat 1,641 cases, of which 19 were cases of nasal polypus. During the same time I saw and operated upon 16 cases in my private practice.

Of these 35 cases there were two under 20—11 and 15 years.

Between the ages of 20 and 30 . . .	9 cases.
" " 30 " 40 . . .	2 "
" " 40 " 50 . . .	12 "
" " 50 " 60 . . .	6 "
" " 60 " 70 . . .	4 "

Twenty were males and fifteen females.

It is essentially a disease of adult life, and occurs more frequently among males than females.

There were two cases under the age of 20, viz.: 11 and 15 years, respectively. These cases were of interest, as showing a somewhat immature development of the tumor. The individual tumor had not developed, but the growth shows, as it were, a cluster of seeds, a small central mass, about which are gathered a large number of small bead-like excrescences.

The peculiar shape of nasal polypi is probably due to their soft consistency. Under the influence of gravity, and perhaps the traction of the to-and-fro movement of the respired air, they are drawn out, as it were, from their attachment, and assume the pear shape which is peculiar to them. They rarely develop to a large size in the nasal cavity, simply because they have no room to grow. Occasionally they spring from the posterior portion of the cavity, and dropping into the pharynx, where they have abundant room for growth, they develop to a very large size, as is seen in the two specimens I show you, nearly the size of a hen's egg. These were operated upon through the nares, but of course removed through the mouth. Their source is usually the middle turbinated bones, but occasionally they are attached to the lower. In only two instances have I ever found a nasal polypus attached to the septum. The attachment is not on the convexity of the turbinated bones, but is in the recess between the under surface of the turbinates and the outer wall of the cavity.

As to the cause of nasal polypus, I know of none. It is a disease of the nasal mucous membrane peculiar to itself. There is certainly no relation between it and any of the constitutional dyscrasie. It is a purely local disease. It is very commonly taught that it is one of the results of chronic rhinitis. It very frequently occurs in connection with rhinitis, but quite as frequently, I think, independently of it. In three cases which I have seen it occurred in connection with atrophic rhinitis, which would certainly argue that it bore no especial relation to the commoner form of rhinitis, the hypertrophic variety.

In a number of instances I have removed single nasal polypi from the border of syphilitic ulcers in the nose, but the cause of the polypi here was not in the constitutional condition, but undoubtedly in the local morbid process.

Symptoms.—As regards the symptoms of nasal polypus, they are familiar to all, and demand no lengthy notice. The prominent symptom, of course, is the blocking up of the nasal passages, together with the profuse watery discharge. Their hygroscopic character, by which they swell up and pour out an increased quantity of watery serum under the influence of damp weather, is well known.

Prolonged, and oftentimes distressing attacks of sneezing is a symptom, the prominence of which is not generally recognized. The irritability of the nasal mucous membrane in chronic rhinitis is usually much diminished, I think, and sneezing does not occur in this affection. The presence of nasal polypi, however, gives rise to these attacks of sneezing in nearly all cases. This is especially prominent in the early stage of the development of these growths, and hence the occurrence of this should always excite suspicion as pointing to this affection.

The occurrence of spasmodic asthma as a reflex symptom due to the presence of polypi in the nose has been noticed only within the last ten years. I am disposed to think this is of more frequent occurrence than is generally supposed. Of the thirty-five cases which I have seen in the last year, four were attended by this symptom. The attacks were those of ordinary spasmodic asthma, giving rise to the same physical signs and attended with the usual nocturnal exacerbations. The asthma is generally cured by the removal of the polypi. In one of my cases, however, in which the disease had lasted two years, the asthmatic symptom was only relieved by the administration of iodide of potassium for about three months after the removal of the polypi. Voltolini first called attention to this reflex symptom of nasal polypus in 1881. Since that time similar observations have been made by Holden, Spencer, Porter, Todd, and others.

Diagnosis.—The diagnosis is usually quite simple. An inspection of the anterior nares with a good illumination revealing the characteristic grayish mass presenting

between the turbinated bones and the septum. In many cases, however, the mucous membrane covering the polypi is of a red congested color, almost identical with that of the mucous membrane over the turbinated bones. In this case a probe will clear up the diagnosis, for by touching the presenting mass it will be found to be freely movable if it be a polyp. This manipulation also reveals the point of attachment, and should always, I think, be resorted to for the purpose of revealing not only the point of attachment of the growth, but also its size.

Treatment.—It seems somewhat strange that the earliest method of removing nasal polypi, that suggested by Hippocrates, should be practised at this late day, but I believe it is a procedure not infrequently adopted. This consists in passing a cord through the nares into the pharynx and out at the mouth; to this is attached firmly a piece of sponge, which is then drawn from behind forward through the nasal passages. This results unquestionably in removing many of the growths, and to an extent in clearing the channel, but it is certainly a very rude and unsurgical method. I saw this operation done in my first year of attendance upon medical lectures, with, I confess, a feeling of admiration for the fortitude of the patient, but far more of dismay at the work for which I was preparing myself. Local applications of astringents, mainly in the form of powders, have been recommended by many writers, the claim being that under their influence these growths shrink up and drop off. The most efficacious of these, it is claimed, is tannin. I have never been able to satisfy myself that local astringents had any but a most temporary influence upon the disease.

Of late years we have seen frequent notices in the journals of the efficacy of injections into the body of a polypus, under the action of which they sloughed off. Acetic acid, tincture of iodine, persulphate of iron, a solution of corrosive sublimate, etc., have been recommended for this purpose. There is no question but a polyp can be destroyed by injecting it with acetic acid or probably many other drugs, but the process is a very tedious one. The injection creates a slough which remains in the passages for from three to five days, giving rise to an offensive odor and fetid discharge. This, of course, is a period of considerable discomfort to the patient. And, moreover, it is not possible to inject more than one or two polypi at a sitting, for it is not ordinarily possible to bring into view but one or two of them. It is then necessary to prolong the treatment over a considerable period of time.

By far the most common method of removing polypi from the nose is by the use of the forceps. They are recommended by the oldest writers on surgery, as well as by most modern text-books. The direction generally given is to pass the instrument up and seize the pedicle. I believe this to be an impossibility. The pedicle of a polyp is generally under the turbinated bone and not on its convexity, and there is very rarely sufficient room to pass the instrument. Moreover, it is not possible to see the pedicle of a polyp. I do not think I have ever seen one until after the growth was removed from the nares. The nasal passages are exceedingly sensitive, and the introduction of any instrument, even a probe, is very painful. The introduction of a pair of forceps, which are made to grope about blindly in the passages until they have seized something, which, as a rule, the operator cannot know whether it be a polyp, or a portion of the healthy tissues, and then their forcible withdrawal with whatever tissue they may happen to have grasped, it seems to me is a most harsh and unsurgical procedure.

I do not think this is an exaggeration. It may be possible to remove a polyp very near the nostril with a pair of forceps without much injury to healthy parts, but the first introduction of the instrument bruises the parts somewhat and excites hemorrhage, and the field then becomes so entirely obscured that any further operating

must necessarily be groping in the dark. Furthermore, I do not think it is feasible, as a rule, to remove all the growths with the forceps. The smaller ones are situated so deeply in the cavity, or are concealed so deeply beneath the turbinated bones, that they cannot be seized. For this reason it is often recommended that a portion of the turbinated bones be removed. I know of no justification for this procedure. The removal of bone involves the removal of healthy mucous membrane also. These tissues have an important function to perform in the nasal cavities and their removal is not justified unless they are diseased. In a majority of cases I believe them to be perfectly healthy in this disease. Even in very extensive removal and mutilation of the turbinated bones by the forceps operation, the polypi are liable to return. The most aggravated cases which come under my notice are those on which the forceps have been used.

As regards the use of the galvano-cautery, as recommended so strongly by Voholini and Middeldorp, it has always seemed to me a ponderous and elaborate method. The use of an instrument in the nasal cavity heated to a white heat, invariably excites great inflammatory reaction, which oftentimes does much mischief. The more I see of the use of this instrument, I am the more inclined to entirely reject it. It unquestionably oftentimes does great harm, and moreover the cases are exceedingly rare in which simpler methods cannot be adopted with far better results.

A very great advance in the treatment of nasal polypi was made when Hilton devised the snare, which has been so extensively used since his day. This was a thoroughly surgical procedure. There were two features of this instrument which impaired its efficiency. It was mounted with soft annealed wire, which was passed over the growth, and the loop being drawn tight the polyp was torn from the attachment. The wire was soft, flexible, and easily bent; it was not easy, therefore, to pass to the base of the tumor. The loop was not sufficiently rigid to manipulate. Moreover, when the polypus was torn away, the polyp tissue being soft and friable, it would give easily and a portion of it would be left, from which a new growth would be liable to develop. The Jarvis snare-écraseur furnishes us with an instrument possessing all the advantages of the Hilton snare, and none of its disadvantages. This is mounted with steel piano-wire which gives us a strong firm loop which can be easily manipulated, and, therefore, carried to any portion of the nasal cavity. A very important feature of this device I believe to be in the principle of the écraseur in contradistinction from that of the snare. The loop is carried over the polyp, and being pressed firmly against the mucous membrane from which the polyp springs the pedicle is slowly severed, and at the same time a small portion of the fibrous tissue of the membrane is torn out. This is very well seen in the specimens I show. I do not believe much in what is called the root of a tumor, but if there is such a thing it is shown here.

Fig. 2.

The only objection I find with the use of the Jarvis snare is that the hand is necessarily in the line of inspection, the instrument being straight. To obviate this I have had constructed the instrument shown (Fig. 2). The tube

is bent in such a manner that the loop can be kept in view during the manipulation. Moreover, it is arranged so that the loop can be drawn up by traction with the fingers until the pedicle is embraced, when the removal is completed by turning the screw. As will be perceived, the device is merely a combination of Jarvis' and Wild's snares.

A nasal polyp, if removed in this manner, does not recur at the point of removal; the whole growth is removed, and no tissue remains from which a new development may occur. Moreover, the operation is accomplished with but little pain or hemorrhage, and by slowly taking one growth after another the nasal passage can be cleared at the first sitting sufficiently to give the greatest relief to respiration. The cavities cannot, however, be cleared at a single sitting. My usual procedure is to continue the operation until the patient is tired, or the passages become too much irritated, and then dismiss my patient for a few days or a week. If hemorrhage occurs a pledget of cotton can be inserted, and the bleeding will be arrested in a few minutes. It is possible with good illumination to see every portion of the nasal cavities. And if a polyp can be seen, no matter how deeply it is attached it can be removed. In this manner, therefore, I believe the disease can be entirely eradicated in usually about six or eight sittings. The question of course arises, Do these growths recur? I do not think they do if they have been thoroughly extirpated. I generally request my cases to present for examination a month after the operations have been finished, when, if I find no growths, I feel quite safe in assuring them that the disease is radically removed.

The principle, therefore, on which this affection should be treated is that of weeding a garden. The whole ground is to be gone over until every vestige of the tumors has been removed.

As to any local application to prevent recurrence, or escharotics to destroy the so-called roots, I do not believe them necessary. I have occasionally used the galvanocautery or acetic acid after operating on cases which had previously been operated upon with forceps, but in other cases I have not found this necessary.

Of the thirty-five cases referred to there has been but one of recurrence. This was a patient whose turbinated bones had been much torn and mutilated by the forceps. It is too early, perhaps, to assert that the other cases are cured. Many of them I have examined since operating and find no evidence of disease. Others were patients at my clinic, of whom I have lost sight. I believe, however, I am perfectly justified in claiming a very large percentage of radical cures by the method described.

ASTHMA.—Dr. Wm. M. Welsh (*Medical Bulletin*) gives the following formula for the treatment of asthmatic attacks:

R	Stramonii foliarum	3 x.
	Potassæ nitratis.....	3 v.
	Seminis fœniculi	3 ss.
	Sacchari	3 ij.

M.

The stramonium leaves and the fennel seeds should be ground to a powder, not very fine, and passed through a sieve so as to get rid of the stems and coarser fragments. All the ingredients should then be rubbed together in a mortar, without producing a very fine powder. The mode of using the material is to place a small portion of the powder on a dish and ignite it with a match. It should burn slowly and somewhat irregularly, emitting fumes as it burns, which, of course, are to be inhaled. The fumes may be conducted to the mouth of the patient by means of a paper hood placed over his head. It combines, the author claims, the good effects of nitre and stramonium.

ŒSOPHAGITIS AS A DISEASE OF INFANCY.

By E. F. BRUSH, M.D.,

ATTENDING PHYSICIAN TO THE NEW YORK INFANT ASYLUM.

HAVING had a case in an infant where death was due to softening and rupture of the œsophagus, in which the ante-mortem symptoms were mistaken for those of another disease, and where the death certificate would have certified to such, had not a post-mortem examination revealed the lesion. I think it is very important that attention be called to the latter, which, taking the most recent books on children's diseases as indications, is hardly recognized. I may add that, having visited the New York Bureau of Vital Statistics with a view of ascertaining its comparative frequency, I found that in the experience of the present official, œsophagitis as a cause of death had never been reported during his connection with the bureau. This ignoring of a previously recognized disease in the ordinary text books is very remarkable when we go back to Billard "On Diseases of Infants," a work written in 1828. This close and accurate observer devotes twelve pages to the consideration of œsophagitis, citing five cases in infants where the autopsy revealed disease of the œsophagus as the cause of death. He says in introducing his remarks on this disease, "This is not a work of imagination—a record of abstract and preconceived ideas—but it is our wish to be a close and faithful interpreter of nature, and to speak only from facts before us. Let us begin, then, with the history, a dry one, it is true, but not the less indispensable, of the facts which we have collected in relation to the diseases of the œsophagus in new-born children." He goes on to say that it is rare in adults, but "is less rare in young infants: the reason of which is that this organ is almost always the seat of congestion to a greater or less extent. On this account it is more disposed to disorganization and inflammation. When inflammation exhibits no other sign than redness, it will be extremely difficult to distinguish it from the habitual congestion of the œsophagus, but when with this redness there are also present some lesions, or some of the products of phlegmasia, no doubt ought to exist that the membrane of the œsophagus is then inflamed. Thus the symptoms which during life accompany the development of these lesions ought to be considered as proper to œsophagitis, and serve to settle the diagnosis of this disease."

The first case he cites is that of a child six weeks old, who had suffered almost from birth from diarrhœa. He first saw her on July 11th, her condition was general paleness, tension of the abdomen, cry feeble but perfect, and constant vomiting without nausea. On the 15th the face became livid, the child refused to drink, and the effort to make her do so caused pain; the milk was vomited almost as soon as given. This condition continued till the 17th. On the 18th the face became pinched, the forehead wrinkled, the cry very feeble, skin cold, pulse scarcely perceptible. Death took place in the night. The autopsy revealed the pharynx injected, the œsophagus of a vivid red at the upper third, on a level with which the epithelium was entirely destroyed, the remainder of the canal presenting a number of red striæ. The mucous membrane of the stomach was of an ash color, and the mucus which covered it thick and very adherent. At the termination of the ilium there were eight slate-colored, tumefied follicular patches. "This child," he concludes, "succumbed to œsophagitis."

The next case is that of an infant six days old. It was first noticed on the 2d of May with an "abundant diarrhœa of green color, almost constant vomiting of glairy matter, frequent regurgitation after drinking." "The child rested in the cradle as if without life." On the 4th it vomited a green liquid in great abundance and died during the night. An autopsy revealed "a well-marked injection of the upper part of the œsophagus

with a longitudinal ulceration at its inferior extremity, six lines long and four broad, the bottom of which was yellow, the borders thick and red, as if bloody, and the mucous membrane was destroyed in the centre of this solution of continuity, the bottom of which was formed by the cellular membrane."

The third case was a child one month old, affected with ophthalmia. This child cried very little, did not appear to suffer much, but vomited almost everything which was given as drink. The constant vomiting continued, the marasmatic condition became profound, a change of position caused a regurgitation of milky fluid, sometimes mixed with white, pasty, grumous matter, and death took place in twenty-two days from the time he first noticed the case. At the autopsy the œsophagus exhibited here and there irregular patches of a bright red and in certain points a complete destruction of the epithelium; there was besides in almost the entire extent of this membranous canal a considerable number of points of *muguet*, the whiteness of which appeared in strong contrast with the intense redness of the œsophagus; this *muguet* ceased at the epithelium.

The fourth case was one of aphthous condition of the œsophagus; the fifth was gangrene of that organ.

All these cases occurred in artificially fed children, which during their sickness had been fed on sweetened gum-water and milk-and-water.

Condie, coming after Billard, the author above quoted, in his edition of 1847 (p. 175), says: "Billard was the first to point out the frequency and describe the diagnosis of œsophagitis occurring in the first periods of infancy." Condie had never been able to verify, by an autopsy, his diagnosis of the disease, but from Billard's description he thinks he has seen several cases. It is safe to infer from this statement that all Condie's cases recovered. This is valuable testimony, as he treated the disease in a manner than which thirty-five years have suggested none better, namely, by injections of milk and broth.

Dr. J. Lewis Smith says disease of the œsophagus in infancy and childhood is comparatively rare. It is most common in infants under three or four months, who are deprived of the breast milk and are given a diet which is with difficulty digested, and perhaps taken too hot or too cold. He has discovered it chiefly at the autopsies of young bottle-fed infants, whose symptoms indicated disease or derangement of the digestive functions. He also says, the symptoms are not well pronounced.

All this testimony is in strong conflict with Vogel, who says it scarcely ever occurs in children under one year of age, because they are too simply fed. Meadows, in his revised edition of Tanner, does not make mention of œsophagitis. West does not include it in his list of infantile diseases. Meigs and Pepper omit it. Steiner devotes three pages to diseases of the œsophagus, but he does not teach that œsophagitis occurs in infancy; he speaks of abscesses, strictures, and so forth occurring in children, but the instances he gives are all traumatic, and he says the diagnosis is easy when the disease is severe.

Since I have had my attention directed to this disease I have performed autopsies on the bodies of eighteen children, and have found lesions of the œsophagus only in the case of two.

In the first instance, that of a child eleven months old, exceedingly nervous and irritable, who had suffered somewhat, alternately from diarrhoea and constipation. It had on September 20th a temperature of 100½° F., four movements of the bowels during the preceding twenty-four hours, frequent moaning and occasionally vomiting. Was ordered half a grain of quinine every two hours. September 21st, temperature 104°, constant vomiting of everything given (foods—beef solution, cooked malt-water, whey, cream, kumyss); tongue seemed swollen and blue; child had only four teeth, which he struck together so violently that they were chipped. All food per mouth was stopped, and three ounces in equal por-

tions of beef-solution and milk injected *per rectum* every three hours. This treatment was began at 10 A.M. The efforts at vomiting continued till about 10 P.M., and the child died a little after midnight. The autopsy revealed both lungs considerably collapsed; the œsophagus dull vermilion color throughout its entire length, presenting the appearance of the fauces when the diphtheritic membrane is torn off; at the junction of its mucous membrane with that of the stomach, there was a white, irregular fringe which hung into the stomach, in appearance being exfoliating mucous membrane; the stomach was small and puckered up, forming deep rugæ, some of which on the top had long lines of recent inflammation. These inflammatory stripes were few in number, and not intense; no other lesions of this organ could be discovered. The duodenum was easily torn, the entire digestive tract below the stomach almost bloodless, consequently presenting a white appearance, except a few inches above the sigmoid flexure, where it was slightly inflamed, and containing the food which had been thrown there a few hours before death. No other prominent lesions were found.

This case I certified to as one of œsophagitis.

My second case was a child, seven months old, bottle-fed, not well nourished. He first came under my notice June 23d, with a mild conjunctivitis and frequent attacks of vomiting. He was undergoing no particular treatment, except that different foods were being tried at intervals, in hopes of finding something which his stomach would retain; he gave no evidence of pain at this time, neither were the bowels disturbed. On July 12th, when making my rounds, I noticed the child in a profound condition of collapse. My attention had not been called to him for a week. In the last few days he had had three or four alvine discharges, green mixed with yellow. Twenty-four hours previously the vomiting had become more violent, and every particle of food administered was rejected, unchanged, almost immediately. We made an effort to put him to the breast, but he would not nurse. July 13th, condition of collapse continues; respiration panting, revulsion to food continues; clonic movements of the entire trunk commenced this morning and continued without any interruption. July 14th, vomiting continues; five movements of the bowels in the last twenty-four hours, watery and mud color. There has been no abatement from the profound collapsed condition; the choreic movements continue, but intermittently; the head is rolling constantly; during the intermission of the movements the left hand is laid on the forehead. July 15th, died this P.M.

Autopsy, eight hours after death.—Pleural cavity on the right side containing about two ounces of food and blood mixed, the odor of the food being quite perceptible. The lung at its approximation to the posterior mediastina was the seat of recent ulceration; that is, there was a soft, ashy gray spot about half an inch in diameter, fading away into the bright-colored lung. The bronchi were plugged with food and mucus, which had found its way there through the trachea, as there were no lesions in the tubes. This lung was collapsed in large patches. Left lung also considerably collapsed, but pleural cavity clear and normal. Two inches above the diaphragm, opposite the lung ulcer, is a small opening through the mediastinal walls and into the œsophagus. Looking at it from this cavity, it looks like a cut across the tube. On removing the tube it was found lacerated about half way across its diameter just within the lower half of its length. Its internal surface was pale and covered with soft catarrhal-appearing mucus. The stomach was adherent to the spleen by strong fibrous bands, and contained some food. There were three invaginated portions of the intestines, none of which appeared to have existed many hours before death.

With regard to this case, I may say that some medical gentlemen who had seen it before death pronounced it a case of cholera infantum.

A case almost exactly parallel to this was reported to the London Pathological Society by Mr. Stanley Boyd. The rupture in his case took place in a child four months old, and he stated that there was no food in the pleural cavity.

It seems to have been a settled question some time ago that these ruptures of the œsophagus are due to post-mortem digestion. This seems untenable when we recollect that these children in whom the ruptures take place are in a feeble condition, and the evidence that the peptonic action of the stomach is suspended is proved by the unchanged condition of the food which is returned from the stomach. We can hardly suppose that a stomach that will not coagulate milk would have the power to digest an œsophagus.

There is no reason why the œsophageal tract should not be subject to special disease, as it is a distinct structure. Its development shows this, for in the sixth week of fetal life it is a tube closed at both ends, and only later joins the stomach and pharynx. Its mucous membrane is different from that of the stomach or pharynx by the fact that it is firmer in texture and paler in color. Its structure is more simple than that of either of the cavities with which it is connected, and therefore is at once less liable to be attacked by disease, and less able to resist disease when it is attacked. It has been compared to the urethra, and the simile is not altogether a bad one, so far as structure and sensation goes, for the pain, as described by those who have suffered from inflammation of either tract, is very similar. Now, as the urethra is subject to special forms of inflammatory action, so is the œsophagus.

But the diagnosis of œsophageal diseases presents far greater difficulties, especially in the infant. There are some classic descriptions of the excruciating pains caused by inflammation of this organ in the adult, which seem to be of such agonizing acuteness as to lead to the conclusion that if they occurred in infancy they would be sufficient to produce shock. I have no doubt that the state of profound collapse in which I found the infant in my second case was caused by the severity of the pain it was suffering, for the rupture in this instance could not have taken place more than a few hours before death, otherwise the pleura would have given evidence of irritation. The evidence of pain in my first case was strongly marked in the facial expression; but, as a diagnostic point of disease in infancy, this, of course, amounts to very little, as it is associated with so many other conditions. Thus far, with my limited knowledge, I would indicate the following points in the diagnosis of œsophagitis: First and foremost, an antipathy to food, and when food is taken lachrymation takes place. This is a point to which attention has not been previously drawn; but when we remember that the ingestion of irritating substances produces tears in the eyes of the adult, we can readily understand that any irritation in the œsophagus may produce them also in the case of an infant. On reference to Billard's first case I notice he says "the cry was feeble but perfect," and we must infer from this that the cry was accompanied by tears; and as in profound gastro-intestinal lesions the cry is unaccompanied by tears, and one of the favorable prognostic indications of recovery from these diseases is a reappearance of tears, a constant lachrymation accompanied by these profound symptoms may be a valuable diagnostic point. Referring to Billard's third case, we find the child affected with ophthalmia, and my second case also was suffering from ophthalmic irritation. There is no doubt that constant wetting of the eye with tears is sufficient to produce conjunctivitis. Even in Gregory's time this fact was recognized. He says "bile and sordes in the stomach have also occasioned ophthalmia. The purulent ophthalmia of infants has been attributed by some to this source;" doubtless by the lachrymation produced by the irritation in the œsophagus. All who have suffered from severe heartburn must remember the tears

that suffuse the eyes when the irritating fluid regurgitates into the œsophagus.

The second important diagnostic sign is the characteristic vomiting; that is, the food taken into the stomach is returned almost immediately and quite unchanged. This vomiting differs from that caused by gastro-intestinal irritation by being apparently unaccompanied with nausea, and it differs from the vomiting due to cerebral irritation by being not so powerfully ejaculated.

These are the two most characteristic diagnostic points. The other points it is hardly necessary, perhaps, to enumerate in this connection, as they simply consist in exclusion.

The question of treatment we need not enter into minutely; but as the disease almost invariably occurs in bottle-fed children, and one of the prime causes is the ingestion of food too hot, it is worth remarking that cold food can be administered to children without any bad effect. This plan of feeding children that require artificial feeding or cold food has been followed for some years by Surgeon King, U.S.A., and highly recommended by him. In my own practice, in cases where children have been entrusted to nurses of careless habits, I have directed the children to be fed with food not warmed, and I have perceived no effects forbidding me to continue to do so.

SOME INTERESTING CASES IN GYNÆCOLOGY.

By HORATIO R. BIGELOW, M.D.,

WASHINGTON, D. C.

CASE I.—On November 30th I was summoned to attend a patient in New Jersey. After arranging some necessary business I arrived on the evening of December 2d (Saturday).

History.—Patient single, thirty-four years of age. Had been treated some years previously for ulceration of cervix, and was operated upon in Philadelphia for stenosis of internal os and consequent dysmenorrhœa. Single and only coitus last May; missed her regular sickness in June. Quickening November 1st. Since November 23d has felt no fetal movement. Muco-purulent discharge, with bearing-down pains for three days prior to my arrival. On December 1st had a free discharge of water per vaginam. Conception took place at first connection, as previously to this, and subsequently, she had no intercourse with her lover.

On Sunday I called Dr. Johnson, of Ocean Grove, in consultation. Manipulation of abdomen defined head in first position, with enlargement equal to sixth month of gestation. There was no fetal heart-beat which we could distinguish. Digital examination disclosed a medium-sized fibrous polypus lying in the vagina, with long pedicle springing from cervical canal. The cervix was ulcerated, and although the external os was widely dilated, the free margin surrounding the pedicle was horny and not easily distensible. During the day the patient had two convulsions, with severe cutting and bearing-down pains, the head slipping down seemed to be pressing upon the internal os, which refused to dilate. Removed polypus on Sunday afternoon with spoon saw. Little or no bleeding. External os well dilated, but marked stenosis of internal os. Pains through the night severe, patient becoming exhausted. On Monday determined to dilate and deliver. Internal os rigid, contracted, and refusing to admit smallest size Peaslee dilator. Introduced smallest size Barnes dilator through external os, hoping to convey dilatation upward by the reciprocal influence of the contiguous structures. Monday night was able to get in the closed blades of Ellinger, and expanded gradually for several hours. Continued dilatation with Barnes' dilators and with two fingers of left hand until Wednesday, then used largest size Barnes, and gave ergot freely. Patient delivered Friday of a dead fetus, already undergoing decomposition. Discharge offensive. Placenta broken down and cord friable. Washed out vagina and

uterus with carbolized water twice a day for two days. Up to this time, one week after delivery, patient is doing well and suffers no inconvenience.

The interesting points of this case, are : 1. The conception following a single, and, as the patient told me, an unsatisfactory and painful coitus, conjoined to a remarkable stenosis of the internal os, complicated by a fairly large polypus. 2. The long duration of labor, and the difficulty experienced in dilating. 3. The subsequent favorable progress of the patient. That no metritis or septic absorption followed delivery may be attributed to good nursing and to the use of vaginal and uterine irrigation with carbolized water.

CASE 11.—*Fibro-cystic tumor*.—On November 15th was sent for by Mary B—, colored, widow, no children, thirty-eight years of age. Nine years ago noticed swelling in lower part of abdomen, which has regularly increased to its present bulk. Has had menorrhagia, hydrorrhœa, numbness of extremities, shortness of breath, and loss of constitutional tone.

Present condition.—The facies uterina described by Kœberlé is well marked. No very general emaciation. The abdominal walls are exceedingly tense, hard, and marked by glistening striæ. The swelling reaches from lower part of abdomen to ensiform appendage. It measures as follows : around umbilicus, 50 inches ; around upper border of tumor, beneath ensiform appendix, 36½ inches ; between ensiform appendix and umbilicus, 45 inches ; around hips and symphysis pubis, 46½ inches ; from symphysis pubis to ensiform appendix, 24 inches. The tumor has a variable consistency, and pressure upward gives the peculiar cystic sensation to the hand. The sound passes four inches into the uterine canal and moves in synchrony with the external abdominal manipulation. The uterus is fixed, prolapsed, and displaced backward ; the solid portion predominates over the cystic ; umbilicus very prominent, which is rare in fibro-cysts, but common to ovarian cysts. Diagnosis : Subperitoneal fibro-cyst ; estimated weight seventy-five pounds ; weight of patient, two hundred and ten pounds. At my request Dr. P. J. Murphy, surgeon in charge of the Columbia Hospital for Women, was kind enough to see the case with me upon the following day, and fully confirmed the diagnosis. Ordered five grains muriate of ammonia, three times a day, with five grains aq. ext. ergot, by suppository, every five hours. Restrict diet to stale bread and meat, with a goblet of hot water at each meal. Persistent friction over abdomen with an ointment of the biniodine of mercury and vaseline. This treatment has been persisted in up to the present time (December 18th), with occasional doses of iron when indicated, and more recently a pill of quinine, arsenious acid, strychnia, and iron to ward off a threatened attack of malaria, to which she is subject. The tumor now measures (five weeks from commencement of treatment), over umbilicus, 49 inches ; ensiform appendix, 36 inches ; between umbilicus and ensiform appendix, 44½ inches ; over symphysis pubis, 46½ inches ; from symphysis pubis to ensiform appendix, 23½ inches. The patient can sit on the chamber and urinate, which she had not been able to do for some weeks. The abdomen is softer and more pliable. The waist-line is more perfectly defined, and there is much less downward bagging. Patient still under observation. The suppositories will be replaced by hypodermic injections of ergotin.

CASE 111.—*Acute antelexion of the uterus*.—Mrs. S—, referred to me by Dr. Boislinière, of St. Louis, who furnished me with the following history : Widow ; thirty-two years of age ; two children, oldest four years ; labors normal ; weight, one hundred and ten pounds ; duration of present illness, eighteen months.

Present condition when examined by Dr. Boislinière.—Menstruation appeared at fifteen years of age, irregular at first ; missed catamenia for six months when sixteen years of age, at a boarding-school in Paris, and again for same period after crossing the ocean. Dura-

tion, about one day ; very scanty in amount ; character, pale ; used to pass clots. Has now grumous discharges ; has pain preceding the flow, which is insufficient and scalds vaginal walls.

Physical examination.—Right ovary prolapsed to side of uterus ; uterus antelexed ; cervix soft and normal in size and shape ; pain at fundus.

By speculum.—Cervical erosion ; white, albuminous discharge from vagina ; discharge from uterine cavity strongly alkaline, from vagina, less so ; marked antelexion ; moderate stenosis of os internum ; depth of cavity, 1¾ inch ; depth of cervix, 1 inch. Location of pain, at fundus.

General symptoms.—Good family history ; stomach, bowels, and lungs, healthy ; slight hypertrophy of heart ; dysuria, diurnal and nocturnal, aggravated by being on her feet.

Diagnosis.—Antelexion ; endometritis ; cervical erosion ; uterine catarrh ; chronic cystitis and vesical catarrh.

Chemical examination of the urine shows : specific gravity, 1.030 ; reaction, slightly acid ; contains mucus and phosphates.

This very full and satisfactory history was entirely confirmed by examination on September 10th, when the patient presented herself at my office. The cystitis was treated with iodoform application to urethra and with the following capsule ordered by Dr. Boislinière :

R. Potass. carb. 3 ij.
Pulv. camph. 3 j.
Allen's ext. bellad. gr. iij.

M. Fill thirty capsules, one to be taken four or five times a day.

I made one application of chromic acid (chromic acid and water, equal parts) and four of a mixture of carbolic acid, iodine, and chloral hyd. to the fundus, at varying intervals. Treated cervix with Churchill's iodine, a paste of subnit. of bismuth and glycerine, and applied tampons soaked in glycerine of tannic acid, and later the same saturated in a mixture of fl. ext. eucalyptus globulus, glycerine, and iodoform, for the purpose of healing the erosions, of depleting the cervix, of relieving pain, and of accustoming the vagina to the presence of a foreign body. The endometritis and cystitis were relieved in about six weeks, and the erosions disappeared under treatment and with the better position of the uterus by dilatation and support. The antelexion was a potent factor in the causation of the cervical erosion and turgidity, acting as a constricting band, while the dysuria was in great measure due to the pressure upon the bladder. I used Gehrung's pessary with much satisfaction, but as it did not accomplish all that I wished I used forcible dilatation with Wilson's instrument, and later made use of the Gehrung, which the patient still wears. The forcible dilatation was followed by no bad results. The patient remained in bed a week or more after the operation and had massage and general faradization. She gains in weight about one and one-half pound each month, has no dysuria or backache, menstruates normally, and is much improved in appearance. The flexion is not yet entirely cured, and probably never will be. Forcible dilatation, if stripped of any subsequent mischief, approaches nearer to a permanent cure than any other measure, but it is very apt to be followed by alarming inflammation. It is difficult beforehand to make out the exact sensibility of any uterus to operative interference. Gehrung's pessary is a most satisfying instrument and gives great relief. I do not believe, however, that under any plan of treatment these cases are ever thoroughly and permanently cured. The question of forcible dilatation is one which every gynecologist must settle for himself ; one man may have unvarying success in a series of cases, while another, equally scientific, will have reason to repent his first operation. This is, in a great measure, due to varying conditions of temperament, which render any operation serious in some people, while in others they are unattended with danger.

Progress of Medical Science.

INTESTINAL CYSTS.—Two theories have been advanced concerning the origin of cysts in the intestinal canal. The first is that they arise from degenerated Lieberkühn's glands through retention of the secretion, the second, that they are due to a process of softening of the solitary follicles. On the strength of careful observations made in a case of this rare affection, Dr. Fraenkel (*Centralblatt für Klinische Medizin*, No. 29, 1882), decides in favor of the former theory. The cysts were due to retention of the secretion in the glands of Lieberkühn, consecutive to a chronic catarrhal inflammation of the large intestine.

NAPHTHOL IN SKIN DISEASES.—Kaposi states that care should be observed in the use of naphthol in skin diseases to avoid surfaces denuded of epithelium, and never to apply it to the entire body. When these precautions are observed, the remedy is wholly without danger, and is of great value in many affections. In eczema it is indicated only in the squamous stage, when the diseased parts are but slightly hyperæmic or even pale. In scabies, one application of naphthol, combined with chalk, green soap, and lard, is usually sufficient for a cure. In the various forms of acne, good results follow the employment of naphthol. The remedy is of especial value in the parasitic affections of the skin, as herpes tonsurans and favus. Pediculi are quickly exterminated by a ten per cent. solution of naphthol in olive oil.—*Prager Med. Wochenschr.*, No. 33, 1882.

CARDIAC TUMOR.—Dr. Manero reports, in the *Gaceta de los Hospitales* of Valencia, an interesting case of malignant tumor springing from the cardiac substance, and protruding as a pulsating swelling through the walls of the chest. The patient was, at the time of his death, aged fifty-one. The first indications of disease appeared four years previously, in the form of constant lancinating pain in the precordial region, without obvious physical signs. In about a year a bulging of the precordial region was noticed, with increased pulsation, attributed to dilatation of the ventricle, and this steadily increased, with increasing pain and gradual emaciation. When seen by Dr. Manero, there was a firm pulsating tumor in the precordial region, about the size of a well-developed virgin breast. It was very painful to touch; the skin over it was healthy. On auscultation of the tumor the normal heart-sounds were heard exaggerated, but not otherwise altered. The pain suffered is described as intense. It seems to have been of the character of that of angina pectoris, and was attended by constant formication in the left shoulder and upper extremity. Death occurred after the patient had been under observation some months, during which time the tumor had steadily grown, without at all involving the skin. No diagnosis was made during life.

At the autopsy the pectoral muscles were found healthy. On removing the front of the thorax, the lower and front part of the pericardium was found to be the cause of the thoracic bulging, which is described as forming a hernia through the walls of the chest, an oval opening being caused by erosion of the third, fourth, and fifth costal cartilages, with portions of the corresponding ribs and sternum. Within this hernial sac of the pericardium, the greater portion of the heart was found enormously enlarged, apparently in all its cavities. It presented on section the appearance of a melanotic sarcoma, in consistence for the most part like that of a sebaceous tumor crossed by pigmented bars and lines, and having numerous large and small pigmented deposits. The growth appeared to be highly vascular. The valves, columnæ carneæ, openings, etc., are said to have been hardly distinguishable. It is not stated how much, if any, of the normal heart-structure was left; neither is mention made of any microscopic examination.

PECULIAR GUMMY TUMORS.—Dr. Lewin, of Berlin, relates (*Charité Annalen*, vol. vii., 1882), three cases in which syphilitic persons had tumors in the palms of the hands, which he considered to be gummata. In the first case, that of a man aged forty-five, who had previously been under Dr. Lewin's care for syphilitic affections of the pharynx and larynx, three swellings appeared several years after contagion, on the right palm, and at a later period a swelling on the second phalanx of the thumb. These swellings, as well as another near the internal condyle of the left humerus, were still present when the man was again seen in 1881, ten years after contagion. All of them were diagnosed by the author to be gummata. Subcutaneous injections of mercury, under which the earlier symptoms had subsided, were prescribed. But after a month there was little change in the tumors. After an interval, inunction of one drachm of mercurial ointment daily was tried, and this also failed to benefit. After a further interval, iodide of potassium was given in a daily dose of thirty grains, gradually increased to forty-five grains. Under this treatment the swellings began sensibly to diminish, some to one-half and others to a quarter of their original size. No further particulars are given.

In the second case, a man, aged thirty, noticed, five years after contagion, two swellings in his right palm, and soon afterward a tumor near the left olecranon. Later still, another swelling appeared near the last, and finally a fifth tumor appeared in the left palm. All these swellings were present when the patient, who also had been treated by the author for his earlier symptoms, returned to consult him. There was now, in addition, a swelling of the size of a hen's egg over the second cervical vertebra. Nothing is said about the treatment or termination of this case. In the last case, that of a man aged thirty, nine years after contracting syphilis, two tumors, about the size of a hazel-nut, appeared in the right palm, and one in the left palm. The swellings were almost as hard as cartilage. There was another swelling near the internal condyle of the left humerus. Under iodide of potassium the swellings became somewhat less hard, but did not diminish in size.

TRICHINOSIS NODULES.—M. Rathery, in *Le Journal de Méd.*, November 4, 1882, describes the case of a man who had numerous subcutaneous nodules of the size of peas, situated exclusively on the supradiaphragmatic parts of the body. On excising one of these tumors, it turned out to be a trichinosis cyst. The patient had never suffered from any general or local symptoms of trichinosis.

HOME-MADE KOUMISS.—The following directions are given for its manufacture: Fill a quart champagne bottle up to the neck with pure milk; add two tablespoonfuls of white sugar, after dissolving the same in a little water over a hot fire; add also a quarter of a two-cent cake of compressed yeast. Then tie the cork on the bottle securely, and shake the mixture well; place it in a room of the temperature of 50° to 95° Fahrenheit for six hours, and finally in the ice-box over night. Drink in such quantities as the stomach may require. It will be well to observe several important injunctions in preparing the koumiss, and they are: To be sure that the milk is pure; that the bottle is sound; that the yeast is fresh; to open the mixture in the morning with great care, on account of its effervescent properties; not to drink it at all if there is any curdle or thickening part resembling cheese, as this indicates that the fermentation has been prolonged beyond the proper time. Make it as you need to use it. The virtue of koumiss is that it refreshes and stimulates, with no after-reaction from its effects. It is often almost impossible to obtain good fresh koumiss, especially away from large towns. The above makes it possible for any physician to prescribe it. The cost is about fifteen cents per quart.—*Chicago Medical Review*.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, January 13, 1883.

THE NEW PHARMACOPŒIA.

WE have already alluded to some of the characteristics of the Pharmacopœia of 1880. A work of so much importance and of so wide a circulation naturally receives much criticism, and we venture to offer here some of the conclusions that have been arrived at regarding it.

For the first time, says Dr. L. Genois, in the *College and Clinical Record*, there has been given a concise but explicit description of vegetable and animal drugs, previous Pharmacopœias having omitted this feature. The new work abandons the old division into primary and secondary drugs and preparations. Instead of this, the list is arranged in alphabetical order.

A large number of articles are dismissed, the total being about two hundred and thirty. Our esteemed contemporary, the *Philadelphia Medical Times*, mourns the loss of many of these in a manner most pathetic, and publishes the entire list, giving them in fact all the obituary ceremonies except a black border.

We hardly share in our contemporary's gloom. With hardly half-a-dozen exceptions, the drugs or preparations omitted we are well rid of. For the rest, there is nothing that will seriously embarrass druggist or physician. Perhaps the latter will most miss the liquor morphiæ sulphatis, and santonin—for which latter the santonate of sodium is substituted.

The number of new articles introduced is about two hundred and fifty. The additions are for the most part judiciously made. A new class of preparations has been introduced which are called "abstracts," a name which we regard as a most unfortunate one. The term "abstract" has become a part of medical periodical literature, and it at once suggests scissors and second-hand articles. To associate it with a powdered drug will require the beating out of new cerebral paths in medical minds.

A prominent feature in the Pharmacopœia consists in the adoption of parts by weight in the processes for pharmaceutical preparations. This change is of more interest to druggists than physicians, however; except as it perhaps foreshadows an adoption later of the metric system.

Valuable tables of the solubility of chemicals in water and alcohol, of saturation of alkalies by acids, and of acids by alkalies, are given.

Some alterations have been made in the relative proportions of active constituents to the finished preparations. The alterations affect chiefly the tinctures, Dr. Genois has drawn up a table showing the most important of

them. These changes will not affect the dosage very much, the actual change even in the opium preparations being less than has been somewhat sensationally announced.

There has been a change made in the terminal nomenclature of the organic alkaloids, the suffix "ina" being uniformly used instead of "ia," as in "quinina" for quinia. This will make little practical difference in prescription writing.

The diluted mineral acids are all to be prepared with a strength of ten per cent. This makes hydrochloric acid one-fourth stronger, and sulphuric acid one-sixth weaker. Spirits of camphor has been weakened one-third. The tincture of aconite root is reduced one-seventh, and its name has been changed to simple tincture of aconite. The extract of aconite is now to be made from the root instead of the leaves, and is said by Dr. Wood to be nearly one-half stronger than the old extract of the leaves.

The Pharmacopœia has been subjected to very searching criticisms, and has come out of the ordeal remarkably well. It is a work requiring a vast amount of technical knowledge, exact and careful statement, and good judgment. All these qualities have been shown by its authors, and it may be positively stated that on the whole, it is the best work of the kind in any language.

TREATMENT OF MALIGNANT LYMPHO-SARCOMA OF THE NECK BY MEANS OF KERN'S CATAPLASMATA.¹

THE very unfavorable results which were obtained in operations, as well as by electrolysis, and from injections of medicated substances (acetic acid, alcohol, solution of iodine, arsenic), caused Prof. Busch to try in some fresh cases of malignant lympho-sarcoma, also in some older ones, the application of Kern's cataplasma, under which he saw buboes reabsorbed while a military surgeon. The poultices of Kern are an admixture of powdered mustard and black soap (1 to 4 or 5), and cause at first a severe erysipelatous inflammation of the skin. They are applied for many hours (four, five, or twelve), enclosed in a small piece of gauze. The cauterized spot is then thoroughly covered with roseline and cotton. A diagnostic error is not to be feared, if one examines for the symptoms of malignant lympho-sarcoma. A person in the prime of life, formerly strong and in the best of health, presenting no previous disposition to glandular affection, is affected with a rapid, increasing swelling of the cervical glands, which coalesces with the surrounding tissues, and thus becomes more or less fixed. It develops through and encloses neighboring structures so as to cause their fusion into a hard, compact mass. Where these symptoms develop in a few weeks, it is sure that a malignant lympho-sarcoma is the explanation of it. In some cases softening, suppuration, and rupture may occur; in others the tumor becomes always softer and more doughy, without producing any fluctuation. It becomes movable, always smaller, and finally disappears through the absorption of its contents. Prof. Busch tries to explain this surprising effect of the irritating poultice on an organized neoplasm.

¹ Lecture of Prof. Busch, Session of the Niederrhein, Ges. für Vtr. d. Hlk., in Bonn, 1880.

Malignant lymphoma consists essentially of round cells, with individual cheesy foci.

A very strong man, aged fifty-three years, observed in the first days of July a hard swelling beneath the left angle of the lower jaw. Presuming it to be an inflammation of the tonsils, he used hydro-therapeutics. On August 13th Prof. Busch was consulted, and was startled at the patient's appearance, as two months previous he was the picture of health and strength. From the middle line of the neck to the spinal column, from the lower jaw to the internal half of clavicle, a hard, already immovable tumor extended. The pulsations of the carotid artery could not be felt, as it was included in its whole course. The larynx was pushed to one side of the middle line. The pains characteristic of these tumors predominated upon the occipital and frontal bones, caused evidently by the continued stretching of the posterior auricular and occipitalis magnus nerves. The voice had become hoarser, on account of pressure upon the pneumogastric or recurrent nerves. Busch states: "With all these symptoms and the extensive, rapid growth of the tumor, I could but express my opinion that in all possibility the patient's life would be terminated in a few weeks. If something had to be advised, I would try the poultices of Kern, which did me great service in light cases; perhaps in this instance they would have no action, and if such should be the case after a few days, there was no necessity to torment the patient." Busch commenced his vacation-trip the next day, turning the case over to Dr. Schaefer for further treatment. The poultice was so well endured by the afflicted man that it remained twelve hours, instead of four or five, upon the tumor. In the evening the burned spot was dressed with roseline and cotton, and morphine given internally. Already, on August 27th (fourteen days afterward), a decided decrease of the tumor and great movability was recognized. The cataplasmata was then continued for only four weeks, and the iodide of potassium was given. As soon as the tumor had nearly disappeared, some iodoform was applied with the brush. Prof. Busch saw the patient again, on October 3d, who was then cured, though he did not expect to find him still among the living.

OBSERVATIONS UPON DIPHTHERIA.

In a paper read before the Berlin Medicinische Gesellschaft, Professor Hensch remarked (*Berliner Klin. Wochenschr.*, No. 40, 1882) upon the innumerable methods of treatment of diphtheria that had been advanced by different writers since the time of Bretonneau. He thought this diversity arose in part from the hope, entertained by many, of discovering a specific remedy for the disease. This hope, the author believed, would never be realized, as it had never been in the case of scarlet fever or measles. Another difficulty in the way of a universal agreement upon the therapy of diphtheria, was the lack of unanimity among authors, as to what constituted the disease. In this connection, Professor Hensch expressed his decided conviction that diphtheria and membranous croup were two essentially distinct diseases. The relation between diphtheria and scarlatina was dwelt upon at length, and illustrated with the

reports of several cases. The speaker incidentally called the attention of his hearers to a point of some importance in the study of scarlet fever. He stated that he had occasionally observed the fever to persist for some days after the disappearance of the scarlatinal eruption. No cause for this continued high temperature could be discovered, and the subsequent course of the disease was without complications. Professor Hensch thought it might be analogous to the evening exacerbations in typhoid fever, after the morning temperature had become normal—the expiring effort, as it were, of the *materies morbi*.

ERGOT IN DELIRIUM TREMENS.

DR. ARNOLDOW (*Deutsche Medicinal-Zeitung*, No. 43, 1882) relates the case of a man suffering from hæmoptysis, who was also threatened with delirium tremens. Chloral had been given for the sleeplessness, but without effect. Upon the administration of ergotine, not only did the hemorrhage cease, but the symptoms of alcoholism also subsided. This happy result induced the author to give ergot in several other cases of mania-à-potu, in all of which the delirium was speedily controlled. Dr. Arnoldow explains this action by the contraction of the blood-vessels of the brain induced by ergot.

THE COLLECTIVE INVESTIGATION OF DISEASE.

We have occasionally referred to the work undertaken by the British Medical Association of collectively investigating various diseases. The method adopted is to draw up cards and explanatory memoranda regarding certain subjects, such as chorea, pneumonia, rheumatism, etc. These are sent to each member of the Association with the request that he answer the inquiries, and return the cards to the secretary. Reports on several diseases for the year 1882 will soon be made.

One cannot read of the work thus mapped out without wishing that a similar line of investigation could be started in America. For the present, however, it seems impracticable. We must wait for some genius to galvanize the American Medical Association into a united body of scientific workers.

DIAGNOSTIC USE OF THE STOMACH-PUMP IN SUSPECTED CANCER.

In the *Centralblatt für Klin. Medizin.*, November 27, 1882, Dr. Rosenbach states that in carcinoma of the stomach a diagnosis may be made by examination of the fluid removed by the stomach-pump or expelled in the act of vomiting. He says that this fluid always, or at least very frequently, contains small particles of the new growth. These pieces may readily be distinguished with the naked eye from other substances found in the matter removed. Their upper surface is dotted with red, reddish brown, or even black, points—the marks of former hemorrhages—the coloration sometimes extending deeply into the substance of the separated particles. This surface is smooth, thereby differing from that of any portion of the mucous membrane, which may have been torn off by unskilful employment of the stomach-pump.

TRANSPLANTATION OF THE CONJUNCTIVA OF A RABBIT.

AN interesting operation was recently performed by Dr. W. S. Little, at the Jefferson Medical College Hospital. It consisted in transplanting the conjunctiva of a rabbit into the eye of a man who was brought into the hospital a couple of months ago, suffering from a severe burn that had entirely destroyed his sight. He is a young Irishman, named Michael McMullin, twenty-eight years old, a strong, well-formed, healthy fellow, but as helpless as a child in his blindness. Shortly after arriving in this country he secured employment in a large laboratory, and while handling strong sulphuric acid the fluid splashed up over his face, head, and chest, burning him terribly, and suddenly and completely blinding him. The right eye was destroyed entirely, and the left one so injured that ankyloblepharon resulted, that is, the lids grew fast to the ball, the burn having destroyed most of the conjunctiva. It was decided to resort to this rare operation, with the hope of restoring the ball and lids to their normal condition, and afterward of securing sight to the injured left eye. Both patient and rabbit were etherized. The eyelid of the man was dissected up and a piece of the rabbit's conjunctiva stitched upon the raw place.

SUCCESSFUL RESECTION OF THE STERNUM.

DR. F. KÖNIG reports in the *Centralblatt für Chirurgie*, No. 42, 1882, a successful case of removal of the sternum, on account of a large osteochondroma. Both the pleural and pericardial sacs were opened during the course of the operation. They were, however, immediately closed with little wads of gauze. The cut edges of the integument were brought in apposition by sutures from below upward, and as the openings into the serous cavities were reached, the wads were withdrawn and compresses applied over the line of suture. The patient made an excellent recovery. The entire sternum, from the manubrium to the ensiform cartilage, was removed. The chief interest of this case lies in the demonstration of the fact that the serous cavities of the thorax may be opened, under proper precautions, without untoward result.

THE EFFECT OF ELECTRICAL LIGHTS ON THE HEALTH.

DR. KRÜSS, at the Hygienic Congress of Hamburg, recently discussed the above subject, and took views somewhat different from those heretofore expressed. He did not think that this light had any injurious effects upon the eyesight. There is doubtless a great difference according as the light is small and steady or large and flickering.

STAMPING OUT DISEASE ON AN EXPENSIVE SCALE.

THE report of the Treasury Cattle Commission, recently made to Congress, describes the sites selected for quarantine stations for imported cattle at Portland, Boston, New York, and Baltimore. The report says that "it is vain to hope that England will remove the restrictions imposed so long, as we fail to show that the last vestige of pleuro-pneumonia has been wiped out from our land," and, further, "that nothing short of the absolute and

undeniable extinction of this disease in the United States will reopen the British market to our live cattle, and save us those millions that we are now every year prodigally, and we might almost say insanely, throwing away." The commission estimates the sum required to stamp out the lung plague at \$2,000,000, and recommends the requisite legislation.

DEATH FROM DICHLORIDE OF ETHIDENE.

A WEAKLY looking man, aged twenty-six, came to the Liverpool Eye and Ear Infirmary for the purpose of having a piece of steel extracted from the lens. He was placed under dichloride of ethidene, and became entirely anæsthetized. Suddenly the pulse became very weak, respiration ceased, and the patient died. Post-mortem examination showed a flabby heart with thin walls, and granular degeneration of the substance.

Ethidene had become quite popular at the infirmary in question on account of its pleasant effects. It had been successfully used four or five hundred times.

DIRECTIONS REGARDING ADMINISTRATION OF MEDICINES.

DURING the past week a girl, fourteen years of age, met her death by poisoning, the result of a misunderstanding regarding the manner in which her medicine should have been administered. She had been suffering from follicular inflammation of the fauces, for which a mixture was prescribed, to be taken in teaspoonful doses three times daily. In addition, the physician, according to the report of the coroner's inquest, told her to get "five cents worth of chlorate of potash, and to dissolve two teaspoonfuls in a tumbler of water." With the latter she was to gargle her throat at intervals. The mother misinterpreting the directions, gave the potash internally in doses of two teaspoonfuls of the saturated solution four times daily, with an equal quantity of the mixture. The day following, symptoms of poisoning developed themselves and the child died in consequence. The coroner's jury exonerated the physician. The disastrous result was evidently due to the mistake on the part of the mother. Had the directions been properly followed, no accident would have occurred. But we cannot help thinking how even this mistake might have been prevented by a little extra pains on the part of the medical attendant in preventing any misunderstanding. This could have been done by giving the directions in writing, and not trusting to the memory of patients or friends. This is a rule with a great many practitioners, and an exceedingly good one. It reduces the chances of misinterpretation to a minimum, causes the medicine to be given properly, at regular intervals, checks haphazard prescribing, and on the whole, although such is the least important calculation, saves a great deal of time for all parties concerned. It is often difficult to remember all the details of treatment in each case. Especially is this so when a number of patients are suffering from the same disease, and the written direction of one may serve at once to refresh the memory for the next visit, and insure accuracy in prescribing which can scarcely be attained by any other means. The written directions should also include those for diet and other details which may be necessary.

A NEW METHOD OF ANTISEPTIC OPERATION.

EVER since the value of certain rigid precautions in surgical operations became fully known, surgeons have been seeking for the perfect antiseptic. This interesting search still continues. We may conclude, therefore, that the substance in question has not yet been found. That it will some day be discovered is a proper subject for devout hope. A completely satisfactory method of insuring antiseptics, or more correctly speaking, of maintaining it, must be conceded to be still forthcoming. Meanwhile, new agents and novel modes of applying old ones are constantly published on the daily bulletin board of medical discoveries. Our German confrères are especially active and proportionately prolific in this department of human enterprise. But, as already stated, the ideal antiseptic has yet to be found.

The most recent method of antiseptic procedure is that advocated by Kocher (*Volkmann's Klinische Vorträge*, No. 224, 1882). He claims that with his method primary union is always obtained, or at least obtainable. The drainage-tube is discarded, and the wound is closed by suture throughout its entire extent. The substance he employs after having made the usual experiments to determine its antiseptic properties is subnitrate of bismuth. The following is the mode of its employment, as described by Kocher:

During the operation the wound is from time to time sprinkled with water, holding the bismuth in suspension. The same is done in any subsequent dressings that may be required. When the operation is completed and all oozing from the cut surfaces has ceased, the wound is closed with sutures and the line of incision sealed with a bismuth paste. Then the usual dressings, wet with the bismuth mixture, are applied. In all large wounds, where there is much oozing of blood or serum, the sutures are inserted, but are not at once drawn tightly. Drainage-tubes are never used, but cavities are filled with wads of gauze. The parts are then covered with the bismuth dressing. After usually from twelve to twenty-four hours the dressings are removed and the surface once more sprinkled with bismuth. The sutures are then tightened and the antiseptic dressings reapplied. This step in the new method is designated as that of "secondary suture" (*Secundärnaht*).

Bismuth in powder is not used, as it was found in some instances to give rise to diarrhoea, nephritis, stomatitis, or other disturbances. It is simply held in suspension in water, in the proportion of ten per cent., and the mixture sprinkled upon the parts by means of a bottle such as is ordinarily used by barbers. In this way the surface of the wound is covered with a thin film of the drug, sufficient to insure antiseptics, without, it is asserted, in any degree interfering with primary union. One great advantage in the employment of bismuth, in addition to its antiseptic properties, lies, according to Kocher, in its astringency. Not only are all septic influences warded off, but the secretions of the wound are dried up, thus facilitating primary union and obviating the disadvantages of drainage. The paper concludes with the histories in brief of a rather large number of cases of severe operations, conducted according to this method. In nearly all rapid healing occurred without suppuration, and with scarcely any rise of temperature. Kocher's procedure certainly

has the great merits of simplicity and ease of application. But time and a more extended trial must determine whether we are to regard it as the long-desired means of securing perfect wound-healing, or whether it is only another of the many ephemeral methods that have proved nearly worthless in all hands save those of their original advocates.

ONE MORE BACILLUS.

At the instigation of Drs. Loeffler and Schütz, of the Berlin Imperial Sanitary Bureau, the etiology of farcy has been carefully investigated. As was anticipated, the specific micro-organism of this disease was soon discovered. Numerous "culture" experiments have already been made, and horses have been successfully inoculated with the isolated germs.

One by one the contagious diseases are wheeling into line. The time seems not far distant when they will have been all safely captured by the bold and ever active bacteriologists.

THE USELESSNESS OF HYPODERMICS OF ETHER IN IMMINENT DEATH FROM HEMORRHAGE.

At the last meeting of the Paris Académie de Médecine (*Bulletin de l'Académie*, December 24, 1882) Professor Hayem read a communication on the above subject. From a large number of carefully conducted experiments he had reached the conclusion that ether produced no appreciable effect upon animals artificially exsanguinated.

On the other hand, transfusion of unaltered blood, or even with blood diluted with serum, often resulted in the resuscitation of apparently dying animals. The practical inference to be drawn from his observations is that in cases of danger transfusion should be at once resorted to, and precious time should not be wasted by watching the effects of ether.

A NEW MERCURIAL FOR HYPODERMIC USE.

AFTER several years of experimental and practical trials, Professor O. Liebreich has at length devised a preparation of mercury, which is especially serviceable for hypodermic use. He announced his discovery at the recent meeting of the Berlin Medical Society. The name of the new compound is formamid of mercury, or *hydrargyrum formamidatum solutum*. Liebreich has found that about thirty injections of a one per cent. solution suffice for ordinary cases of syphilis. Given internally, the drug is inert.

THE STATE OF THE LUNGS IN PLEURISY.

IN an article on the state of the lungs in pleuritic attacks, Dr. Grancher (*L'Union Médicale*) expresses the opinion that the physical signs over the upper part of the chest are not given sufficient attention in this disease. Thus he states that if the lung be healthy, the subclavicular tympanic resonance will be found to correspond with an increase of the vocal fremitus and respiration. If, on the other hand, there is congestion, then respiration is generally weak; and this happens most frequently in tubercular cases. He points out also that both the vocal vibrations and the respiration may be diminished from various causes. Most prominent among these he finds is pulmonary oedema and compression of the bronchi.

News of the Week.

CONVICTION UNDER THE ADULTERATION ACT.

THE first conviction for selling adulterated food was obtained by the Health Board of this city, on Tuesday. The charge was made against Henry Fulle, a grocer, for selling adulterated cream of tartar to Dr. E. G. Love. It was proved that the particular article contained ninety-five per cent. of gypsum and five per cent. of tartaric acid. It was obtained by the retailer from a wholesale dealer, who had disposed of large quantities. One man present in the Court-room said that he alone sold every year \$180,000 worth of the alleged adulterated article to the trade. The case was a perfectly clear one for the prosecution, and the ruling was in strict accordance with the evidence offered. The defendant's counsel, who also represented the interests of the wholesale dealers, took some curious exceptions in the course of the trial. It was necessary for the prosecution to fix upon a standard of purity for the article alleged to be adulterated. Accordingly the United States Pharmacopœia was put in evidence as the authority. The defendant's counsel refused to admit such evidence, claiming that there was no direct proof that the volume in question was the one published by the authority of the pharmacopœial convention. They refused to be satisfied until the original minutes of the Convention authorizing the publication should be produced. Of course, this was a mere legal quibble in the face of the sworn testimony of experts, regarding the identity of the book, and the objection was overruled. It is understood, however, that the case will mainly be carried on this point upon appeal. A fine of ten dollars was imposed upon the vender of the article, who was paroled into the custody of his counsel. The Board of Health deserves great credit for the manner in which it has conducted the prosecution, and proves its eminent fitness for handling similar cases. So far a good precedent has been established.

PRACTISING WITH A DEAD MAN'S DIPLOMA.

THE act to regulate the practice of medicine in Illinois has, since its enforcement, exposed over thirty individuals who have been falsely swearing to be graduates of foreign universities. The most recent case of the sort was that of a barber who assumed a dead doctor's name (Henry A. Lüders), and who practised with the dead man's diploma. The latter was issued to Dr. Heinrich Andreas Lüders, May 15, 1866, by the University of Göttingen. The pretender presented the diploma for verification, but owing to some informalities in the affidavit, no certificate was issued at the time. The diploma was found to be a genuine document, and being finally accompanied with recommendations as to the professional character of the holder, a certificate was finally issued to him by the State Board two years after his first application was made. After a time suspicions were aroused concerning the medical qualifications of the man and his right to the diploma in his possession. Inquiry was made of the dean of the University of Göttingen, resulting in the answer that the real Lüders had graduated in 1866 and had died in November, 1878. These facts coming to

the knowledge of the State authorities, it was resolved to prosecute the quack for felony. Unfortunately, before this could be done the sham doctor escaped.

It has since been learned that the rascal's proper name is Lambrecht, and that he is a barber by trade; but how he became possessed of the real Dr. Lüders' diploma and other papers has not yet been ascertained. The letters of recommendation finally forwarded by the fellow are pronounced forgeries.

Some shocking instances of the miscreant's malpractice have come to light since his flight, among the most recent being the brutal butchery of a mother in labor and her unborn offspring. From the testimony of friends of the unfortunate woman, it appears that he used a stick and piece of string, in place of forceps, and, failing to effect delivery by this means, he eviscerated the infant with a common, rusty case-knife, finally hacking it to pieces with the same instrument and taking it away piecemeal. The wretched mother was terribly injured during this performance, and died shortly after.

The villain is now at large, and will doubtless settle in some adjoining State having no medical registration act.

ADULTERATED TEA.

A BILL has been introduced into Congress to prevent the importation of adulterated tea. This bill has been drawn up by a number of prominent importers who claim that some positive measures are needed to keep out of this country the vast amount of tea and rubbish now sent here. Of the total yearly importations of tea, which amount to about eighty million pounds, we are told that twenty per cent. is unfit for healthy consumption. The actual yearly consumption of tea in the United States is only 65,000,000 pounds, so that if rubbish were excluded there would still remain enough to supply our needs.

England has passed a law similar to the one now desired in this country. As a result, in 1881, 44,443 packages of tea were refused entrance, and no doubt a large part of this finally reached the United States, forced upon the country by cheap auction sales and palmed off as good to the poorer classes.

There is nothing in the real facts of tea adulteration to cause alarm or start a sensation. Tea is very rarely adulterated. Among sixty-one samples examined by Dr. S. A. Lattimore, for the New York State Board of Health, no foreign substances were found. Many of these were of the cheapest and most inferior quality, however; and there is no question that vast amounts of such tea-dregs and rubbish are foisted upon us. The country should be protected from such impositions, but whether the health is really injured by cheap tea may be questioned.

THE NEW YORK COUNTY SOCIETY AND THE PROSECUTION OF QUACKERY.

THE last fasciculus of the published minutes of the Society has been distributed to members. It includes the minutes of the September, October, November, and December meetings, and one of its most interesting features is the report of the Board of Censors, which includes the report of Mr. Ripley, the Counsel of the Society. In it we find that a score or more of illegal practitioners have been successfully prosecuted under

the Medical Act of 1880. Most of them were fined and compelled to seek other pastures. This was accomplished at an expense to the Society of less than eight hundred dollars, and yet we noted that at the annual meeting there were members who objected to the special assessment of two dollars which is requisite to the further prosecution of the good work. In other words, there are members of the society who appear to be unwilling to curtail quackery at an individual expense of about ten cents per quack.

In this connection we may note that the entire expense of the attempt to rid the city of illegal practitioners has been borne by the members of this Society.

We cannot too highly commend the energy and activity displayed by the officers of the New York County Society, and have every reason to believe that it will be maintained during the present year.

SUFFOCATED BY A SHIRT-STUD.

EDWARD OLIDER was suffocated last week by a shirt-stud which he was holding in his mouth and which accidentally found its way into the trachea. This is the old story with persons who persist in using the mouth as a convenient receptacle for all sorts of foreign articles. Of course immediate tracheotomy would have saved him, but unfortunately the means to the end were, as usual, not at hand.

ADULTERATED MILK.

SEVERAL wealthy farmers around Camden, N. J., are being prosecuted for selling adulterated milk. The chances are that the jury will find it hard to agree on a verdict, as the ordinary Jerseyman has had comparatively small experience in testing lacteal fluids in their purity. Even to settle on the average standard would require the consideration of very many qualifying conditions.

THE SANITARY CONDITION OF NEWPORT, R. I.

IT would appear from reports recently received that the sanitary condition of Newport is far from what it should be. The Newport Sanitary Protective Association, which has during the past year been so active in its efforts to remedy the sewerage of that city, has just published a document, in which it advises all persons who intend to hire houses or parts of houses in and around Newport, to ask for evidence that the premises have been pronounced safe by one of their inspecting engineers. It is understood that the recommendation is to be applied to all hotels and boarding-houses. The plan is certainly a good one if it can be consistently carried out, and under the latter conditions it commends itself to the attention of sanitary committees everywhere.

NOTIFICATION OF INFECTIOUS DISEASES IN LONDON.

WE learn from our London correspondent, in a letter, dated December 28th, that the question of notification of infectious diseases is being warmly agitated in the medical circles of that city. The opposition to the measure is evidently on the increase. The element of compulsion is the notable and objectionable one. Aside from this, it is claimed that it makes doctors spies on, and informers against, their patients. The latter, in the way of pre-

venting trouble, will be induced to conceal a case of infectious disease, and struggle through without a doctor, rather than be informed against. It is also urged that it increases the number of certificates medical men will have to write, either for nothing, or, at best, for a nominal fee; that, in some cases, medical officers of health have taken advantage of their position to interfere with the patients of another medical man; that questions may often arise as to accuracy of diagnosis, and discredit be thus cast upon the family attendant. For instance, the medical man may find himself in doubt as to whether a given case is, or is not, scarlet fever. "If I notify," he says, "and it turns out not to be scarlet fever, I shall have annoyed my patient for nothing, and the medical officer of health may call and have the opportunity of blaming me before my patient or his friends for an error in diagnosis. On the other hand, if it is the disease and I do not notify, I shall be fined." The objections are certainly well taken.

TRAIN-WRECKING AS A CAPITAL CRIME.

ASSUMING as correct the comprehensive and octopus-like character of certain recent descriptions of insanity, it is hard to see how a train-wrecker can ever be proved sane. With due respect to science, however, society is obliged to look at these men for the present as vicious and responsible; and Governor Butler, in his inaugural, urges that laws be enacted for their suitable punishment. "There is," he says, "one crime which indicates such depravity of heart, such disregard of life, such malice toward all mankind, that the doing of it should be visited with the swiftest and most condign punishment."

Every one will, we believe, approve of this sentiment, and heartily wish that the legislation asked for will be granted.

MEDICAL REFORM IN MASSACHUSETTS.

GOVERNOR BENJAMIN F. BUTLER, of Massachusetts, in his inaugural address discusses many vital questions of reform pertaining to State government. Altogether, he proves himself to be a man of large grasp, and one who thoroughly appreciates the necessity for radical reforms in the management of State charitable institutions. The abuses in regard to the latter to which he calls attention are those connected with the difficulty of fixing responsibility for mismanagement where it should properly belong. In this connection he takes occasion to protest against commissioners in general. His argument is that these commissions shift responsibility from one member to the other. In this way the whole Board allows acts and expenditures which no single responsible person would have dared to tolerate.

As to the mooted question whether the conjoint Board of Lunacy, Health, and Charity shall be divided into independent bodies, we gather that the Governor would dissolve the whole organization, and substitute single responsible individuals.

Governor Butler is certainly right in many of his charges against Boards, Commissions, and Committees. There are, however, a good many objects for which such bodies can work much better than single persons. And many of General Butler's objections could be met under

a system which made Boards more directly responsible than is usually the case.

We regret not to find any reference in the message to the subject of medical legislation and registration. Our Massachusetts brethren will be derelict if they allow the session to pass without an attempt to render impossible such institutions as the Bellevue Medical Hospital of Massachusetts.

DR. WILLIAM HUNT'S ADDRESS BEFORE THE PHILADELPHIA ACADEMY OF SURGERY.—On Monday evening of this week the annual address of the Philadelphia Academy of Surgery was delivered by Dr. William Hunt, Surgeon to the Pennsylvania Hospital. He discussed Es-march's criticism of American surgery, contained in the latter's recent lecture on President Garfield's wound. The assertions and strictures of the German Professor, after being translated by Dr. Hunt, were commented upon in a very witty manner, and rebutted by points from the well-worn pages of the history of the case. The hackneyed and unsavory subject was given renewed interest by Dr. Hunt's novel treatment of the theme; but the value of prolonging such discussions is questionable. The latter part of the address was devoted to Koch's bacillus tuberculosis. The lecturer expressed doubt as to its etiological relation to phthisis, though he did not deny its existence. In an adjoining room were exhibited a large number of microscopic preparations showing the bacilli of Koch, and the pseudo-bacilli of Schmidt, of New Orleans. Schmidt, as our readers know, affirms that the bacillus described by Koch is nothing but a fat-crystal. The pseudo-bacillus slides shown were prepared by Schmidt himself. Some of the others were prepared, we believe, by Koch, or those who had worked under his supervision; hence, an opportunity was given for those present to compare the objects seen and described by the two micrologists.

Even to untrained eyes it was apparent that Schmidt had never seen what Koch has described. In other words, the pseudo-bacilli of Schmidt, shown in his own preparations, are said not to resemble the bacilli of Koch, as shown in his preparations. Hence, Schmidt's deductions must be erroneous; for he evidently has not seen a true Koch bacillus to compare with his own so-called pseudo-bacilli which are doubtless nothing but fat-crystals.

NEW YORK ACADEMY OF MEDICINE—ELECTION OF OFFICERS.—At the annual meeting, held January 4, 1883, the following officers were elected: *President*, Fordyce Barker, M.D., LL.D.; *Vice-President*, H. P. Farnham, M.D.; *Recording Secretary*, W. H. Katzenbach, M.D.; *Corresponding Secretary*, J. G. Adams, M.D.; *Treasurer*, William F. Cushman, M.D.; *Trustee*, Gouverneur M. Smith, M.D.; *Treasurer of Board of Trustees*, Charles Wright, M.D.; *Member of Committee on Admissions*, E. L. Partridge, M.D.; *Member of Committee on Ethics*, H. E. Crampton, M.D.; *Member of Committee on Education*, J. C. Dalton, M.D.; *Member of Committee on Library*, A. McLane Hamilton, M.D.

AMENDING THE PENAL CODE.—Already two bills have been introduced into the Assembly amending the Penal Code. One of them, by Assemblyman Murphy, compromises the matter somewhat by striking out the flagrant

absurdities, and the other, by Assemblyman Campbell, advocates the freest possible license for trade. The latter measure is one which the Puritanical code makers have deliberately precipitated.

NEW YORK OPHTHALMOLOGICAL SOCIETY.—At the Annual Meeting, held January 8, 1883, the following officers were elected: *President*, George R. Cutter, M.D.; *Vice-President*, David Webster, M.D.; *Secretary and Treasurer*, Jas. L. Minor, M.D.

CHARITY HOSPITAL, NEW YORK.—At the annual meeting of the Medical Board of Charity Hospital, at the Academy of Medicine, the following officers were elected for the current year: *President*, Dr. John H. Ripley; *Vice-President*, Dr. T. F. Ferguson; *Secretary*, Dr. Edward S. Peck.

THE SPREAD OF SMALL-POX.—Small-pox has, during the last two or three days, spread from Baltimore to several small ports along the Chesapeake Bay. The disease has also broken out in the lumbering shanties in upper Ottawa, Canada, and the woodmen are dispersing to neighboring districts.

NEW YORK PATHOLOGICAL SOCIETY.—The following officers were elected at the annual meeting held on the evening of January 10th: Dr. George F. Shrady, President; Dr. R. E. Van Gieson, Vice-President; Dr. Wesley M. Carpenter, Secretary; Dr. John H. Hinton, Treasurer, and Dr. John C. Peters, Editor of Transactions. Drs. F. R. S. Drake, J. H. Ripley, J. H. Hinton, V. P. Gibney, and J. C. Peters, Committee on Admissions and Ethics; Drs. J. C. Peters (Editor of Transactions), W. M. Carpenter, J. H. Hinton, E. C. Wendt, Beverly Robinson, and the president, Committee on Publication.

NEW YORK'S WATER SUPPLY.—The Mayor of the city of New York is requested by the State Assembly to select and appoint immediately five citizens of this city, who, in conjunction with himself, shall without delay examine into a plan for increased water supply, and report to this body within twenty days as to the practicability of the proposed plan, the probable cost, the time required for its execution, and such other views and recommendations as they may deem proper.

PROFESSOR SCHROEDER OF BERLIN.—It is authoritatively denied that Professor Schroeder, of Berlin, has been summoned to London to attend the Princess of Wales.

TYPHOID EPIDEMIC IN LONDON.—London is suffering from the effects of a slight epidemic wave of typhoid fever, the weekly deaths varying from 31 to 42. The disease is said to be more malignant than is usually the case.

DR. WARREN STONE, a prominent physician of New Orleans, died suddenly on January 3d. The deceased was thirty-nine years of age.

SMALL-POX IN ATLANTA.—A telegram from Atlanta, Ga., states that small-pox which appeared in that city two weeks ago is spreading, and among the whites. No precautions are taken by the authorities to suppress the disease, the pest-house wagon being driven at all times of the day through the most crowded and unprotected thoroughfares.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, December 13, 1882.

GEORGE L. PEABODY, M.D., VICE-PRESIDENT, IN THE CHAIR.

(Continued from page 21.)

DR. W. GILL WYLIE presented a specimen of
CYSTIC FIBROMA OF THE OVARY.

"M. D.—, aged twenty-four, single. I first saw the patient in June, at the request of Dr. S. Baruch. At this time she was in good general health. On examination, a very firm abdominal tumor, about the size of a coconut, was readily made out. It was freely movable, and was not directly attached to the uterus, which was normal in size.

"On account of the season and the small size of the tumor, and absence of pain and other serious symptoms, she was advised to wait until the fall for its removal. During the summer, in August, she had a sharp attack of peritonitis, and was in bed several weeks.

"September 20th.—She was admitted to my ward at Bellevue Hospital. The tumor had increased to several times its former size, and was firmly fixed in place, and to some extent painful to touch.

"October 17th.—About six weeks after acute peritonitis had subsided the tumor was removed. The usual incision in the median line was made. The peritoneum was very much thickened, and the whole surface of the tumor was covered with adhesions. About a gallon of dark bloody fluid was evacuated by a trochar, and the tumor was then slowly pulled out of the incision. The adhesions were torn loose, and when thick or strong were put upon the stretch and divided by actual cautery. When the pedicle was reached it appeared to be attached to the right Fallopian tube; it was firm and much smaller than was expected in a tumor so vascular and with such thick walls. The pedicle and two ragged ends of the omentum were tied with silk ligatures and dropped back in the abdomen. The wound was kept open about an hour after this, in order to clear the cavity of all blood, and a glass drainage-tube was inserted and the wound closed with silk sutures.

"Patient was not allowed any food for forty-eight hours, and only small quantities of water in drachm doses were given for intense thirst. After this she was fed on koumiss, and after a few days other food.

"She recovered without a bad symptom, and in ten days was removed to the general ward from the rooms used for such cases.

"One point of practical importance was discussed before the operation, namely: In case of peritonitis complicating ovarian tumors, when one has the choice, at what time is it best to operate? Should the operation be done a short time after the peritonitis, or should it be longer delayed? In this case the adhesions were extensive, but were not tough, nor so difficult to separate or tear loose as in those cases which I have seen the operation done long after peritonitis. I have seen four cases where the adhesions were so strong, compared with the sack of the tumor, that most of the sack could not be removed, and after a part had been cut away the remainder was sewed to the edges of the abdominal wound and the cavity washed out once in eight hours with a drainage-tube. All of these cases gave a history of chronic peritonitis, and all recovered.

"In dealing with adhesions much depends upon the thickness and strength of the walls of the tumor; and the strength of the adhesions will depend upon the duration of the peritonitis."

Report of examination made by Dr. W. H. Welch.—"The tumor is a unilocular cyst measuring 18 ctm. in diameter. The wall of the cyst varies in thickness

from 2 to 10 mm. Its average thickness is about 3 mm. The external surface of the tumor presents nearly everywhere the remains of old adhesions in the form of membranous shreds. In other respects this surface is smooth and glistening. From a point corresponding to the attachment of the pedicle of the tumor proceeds a hard fibrous cord 3 mm. in diameter, which can be traced for a distance of 10 ctm. over the surface of the tumor, with which it is closely incorporated. This cord probably represents the remains of the Fallopian tube, but it is impervious. Near the same situation a sessile mass projects from the surface of the tumor. This measures 4 ctm. in length, 2 ctm. in breadth, and 2½ ctm. in height. It has much the shape and appearance of an ovary externally, but internally it consists of a soft reddish mass.

"The wall of the cystic tumor is not divisible into separate layers, but presents throughout its thickness the appearance of dense fibrous tissue. The inner portion of this wall, however, is in most places of a reddish-brown color, indicating old extravasation of blood in this situation; the outer portion of the wall is gray in color.

"The inner surface of the cyst is thickly set in most places with little fibrous elevations, often pedunculated, and looking like papillomatous growths. These little growths are firm in texture and of a reddish color, like the inner portion of the cyst wall from which they spring.

"There are no evidences of secondary cysts in the wall of the main cyst, so that the tumor is strictly unilocular.

Microscopical.—"The most careful examination of the inner surface of the cyst, both in the fresh state and upon section after hardening, fails to reveal any epithelial lining.

"The wall of the cyst is made up throughout of dense fibrous tissue. The connective-tissue fibres are coarse and interlace in all directions, but have a tendency to run parallel to the surface of the cyst. Between these fibres are fusiform and branched connective-tissue cells, with, in places, a considerable number of round cells. There are also blood-vessels to be observed in the wall. The inner reddish-brown portion of the cyst wall is composed of dense fibrous tissue, with few cells, but with an abundance of yellowish-brown pigment granules (hæmatoidin) between the fibres. The papillomatous excrescences are made up likewise of fibrous tissue with blood pigment. Further than the blood-pigment there is no especial difference in structure between the outer and the inner portion of the cyst wall.

"An interesting feature in the anatomy of the tumor is the presence of rows of cubical epithelial cells upon its external surface. These epithelial cells resemble those covering a normal ovary. They often lie imbedded in the tissue in consequence probably of the growth of adhesions over and around them, in this way they often appear to line spaces like glandular cavities. There is nothing resembling them in the inner portion of the cyst wall. Smooth muscular fibre is found only in the cord representing the Fallopian tube.

Diagnosis.—"The tumor is probably a cystic fibroma developing from the ovary. The ovarian origin is rendered probable (aside from the relations noted at the time of the operation) by the relations to the Fallopian tube, by the presence of cubical epithelium in the outer wall of the cyst, and perhaps by the existence of a portion of the ovary in the outer wall of the cyst. The last point, however, cannot be established positively in consequence of the destruction of the parenchyma by old hemorrhages.

"The fibromatous character is established by the structure of the cyst wall and the absence of any epithelial lining to the cyst. The tumor is certainly not an ordinary ovarian cystoma. The uniform character of the cyst wall, the absence of epithelium on the inner surface, and the unilocular structure, preclude this.

"The mode of development of the cyst cannot be determined. Extravasations of blood would seem to have played a rôle in this process, as evidenced by the abundant blood-pigment in the inner portion of the cyst wall.

The fluid contents of the cyst were not sent to me. They are said to have been thin, watery, solid, and of a reddish-brown color."

DR. J. LEWIS SMITH presented a larynx and trachea which illustrated

DIPHTHERIA COMPLICATING SCARLET FEVER.

One point of interest in the clinical history was the clearness of the voice; so much so that the existence of a pseudo-membrane in the larynx and trachea was not suspected. The membranous exudation was shown distinctly upon the inner surface of the trachea and larynx. The question arose, was it diphtheria complicating scarlet fever, or was there a scarlatinous pseudo-membranous laryngitis and tracheitis? Dr. Smith thought the nature of the condition was not yet fully understood, but inclined to the opinion that this was a case of diphtheria complicating scarlet fever.

CHRONIC BRIGHT'S DISEASE—DILATATION OF THE HEART—PERICARDITIS.

DR. BEVERLY ROBINSON presented the heart and kidneys taken from a woman who presented during life the physical evidence of enlargement of the heart without valvular lesion, double pleurisy with effusion, and chronic Bright's disease. They were accompanied by the following history, furnished by Dr. Charles Beach, junior assistant on the medical division of St. Luke's Hospital:

H. G.—had had numerous rheumatic attacks, involving one or both ankles. The last attack occurred eight months ago, when the knees were involved. It lasted six weeks. She had never had any cardiac symptoms. In July, 1882, she was exposed to cold and damp air, since which time she had been failing in strength. Micturition had been frequent, spots floated before her eyes, and she had suffered from nausea. Two months ago she began to have dyspnoea, somewhat paroxysmal in character, and oedema of the feet, legs, hands, and face appeared. At various times she had had moderate pain in the left side of the chest. On admission the patient had marked oedema of the face and extremities, was suffering from extreme dyspnoea, had a very weak pulse, no appetite, and her temperature was elevated. Digitalin and whiskey were administered hypodermically. The urine had a specific gravity of 1.010, acid reaction, contained fifteen per cent. of albumen, but the microscopical examination was negative. Both pleural cavities were about half filled with fluid. Examination of the heart was negative. Thirteen ounces of fluid were withdrawn from the right side of the chest. Immediate and marked relief followed. Examination by Dr. Robinson: Respiration 32, pulse 108 and tense, the apex beat could not be felt. Pericardial friction-sounds were heard midway between the apex and the left border of the sternum. The first sound of the heart was prolonged. There was evidence of pericardial effusion, and also of fluid in the left pleural cavity. The spleen was slightly enlarged. The dyspnoea was believed to be chiefly uræmic. A milk diet was ordered. Half an ounce of whiskey was administered every six hours. One minim of a one per cent. solution of nitroglycerin was ordered every four hours.

October 27th.—The patient had a chill this morning lasting fifteen minutes; also vomiting. During the last twenty-four hours she has passed sixteen ounces of urine. The nitroglycerin was reduced to one drop three times a day. The vomiting persists. The bowels were moved by enemata, cups were applied to the loins.

November 1st.—Physical examination revealed dulness up to the angle of the scapula. Nitroglycerin was discontinued. Over the apex of the heart there could be heard, on inspiration and expiration, a rubbing sound, not affected by the heart motion, but still believed to be probably pericardial. The urine had a specific gravity of 1.008, neutral reaction, and contained thirty per cent. of albumen. The patient had passed twenty-four ounces during the past twenty-four hours.

On November 2d the cardiac sounds were distant and indistinct, crumpling sounds were still heard. Cardiac dilatation, localized pericarditis. Whiskey was continued three times a day. The fluid extract of convallaria, ten minims, were administered every six hours. From November 4th to November 9th the patient received whiskey and the fluid extract of convallaria and the quantity of urine passed varied from twelve to twenty-two ounces in the twenty-four hours. On that date pericardial friction-sounds were noticed preceding the second sound of the heart. Pulse, 96.

On November 11th the right side of the chest was aspirated and thirty-five ounces of fluid were withdrawn. On November 12th the patient passed ten ounces of urine which had a specific gravity of 1.014, was alkaline, and contained sixty per cent. of albumen. On November 15th the oedema of the feet and legs had increased. On November 16th there was oedema of the vulva. Patient passed fourteen ounces of urine. A creaking sound was heard over the pericardium. November 18th the pericardial friction-sound had almost entirely disappeared. The patient's pulse was 72 and regular; she passed twelve ounces of urine. The convallaria and the iodide of ammonium which had been administered since November 8th, in doses of two grains, were then discontinued. On November 19th the hot-air bath was administered. On November 20th the patient passed only eight ounces of urine, and had pain in the back and lumbar region. From this date to November 22d there was no marked change in the condition of the patient, and on the 24th she died.

At the autopsy the abdominal walls were found infiltrated with serum, and the abdominal cavity contained about eight ounces of fluid. There were about ninety-eight ounces of serous fluid in the pleural cavities. There was about one ounce of serum in the pericardium, over the apex of the heart anteriorly. Just to the left of the septum was a small patch, about the size of a split pea, of thickened plastic exudation. On the posterior surface of the aorta, just above the reflexion of the pericardium, were seen patches presenting the same appearance. The right ventricle was distended and contained dark and white clots. The left ventricle was hypertrophied. The valves were apparently normal. The heart weighed fifteen and a half ounces. The lungs were more or less compressed and the pleura was thickened. The spleen was enlarged and the capsule thickened, weight nine ounces. The capsule of the liver was thickened, especially about the inferior ligament, and the surface showed white streaks with some increase of connective tissue. The kidneys were the seat of chronic diffuse nephritis. Both were reduced in size, the left weighing only an ounce and a half. There were cysts in both ovaries.

Dr. Robinson also presented the *heart and kidneys* from a patient who was admitted to St. Luke's Hospital, December 10, 1882. They were accompanied with the following history, furnished by R. J. Devlin, Senior Assistant on the Medical Division. The patient was forty-four years of age, and was able to give only an imperfect history. His first and only attack of rheumatism occurred seven years ago, which involved the ankles and hands, and lasted, including relapses, four months. He had never suffered any pain or distress in the region of the heart, nor palpitation. During the last two years he had been obliged to rise from four to six times during the night to pass water. No change had been noticed in the appearance of the urine. The patient thinks that the daily quantity has been excessive. During the last six months he has suffered considerable from sweating and diarrhoea. Last August he was seized with sudden failure of vision in the left eye, followed in about two months by similar changes in the right eye, and at the time of his admission his vision was not sufficiently good to enable him to read print. Oedema of the extremities appeared for the first time two months ago. On December 2d, the abdomen being very tense, he was tapped, and twenty ounces of fluid were removed.

From this date to December 8th there was a gradual decline of the patient, pericardial friction-sounds and valvular murmurs were distinctly heard, the œdema increased, there was no increase in the flow of urine, the patient became delirious, finally comatose, and died. At the autopsy there was found some thickenings of the cardiac valves, with atheromatous degeneration of the anterior coronary artery, and the kidneys were the seat of cystic degeneration.

Dr. Robinson directed attention, especially in connection with the first case, to the use of convallaria and nitroglycerin. Both these remedies were used, and there was no noticeable increase in the quantity of urine passed. Evidently under the influence of convallaria the cardiac action was increased in force and the heart was made to do its utmost, and apparently the woman would have been benefited except for the condition of the kidneys. While the patient was taking the iodide of ammonium a pericardial friction-sound disappeared, and at the autopsy it was believed that the evidence of disappearing pericarditis was found.

Dr. WYETH asked whether there was anything in the condition of the kidney which explained why the digitalis and the other remedies did not increase the secretion, but at the same time increased the force of cardiac action.

Dr. ROBINSON believed that in those cases where we find a low specific gravity of the urine, and its quantity cannot be increased by the best known cardiac stimulants, we have reason to believe that the atrophic kidney exists, and he should be prepared to assume that with a small quantity of urine with nothing specially abnormal about the specific gravity, and failure on the part of the kidneys to respond to cardiac stimulants, as in the case recited, we might reasonably expect to find that form of kidney degeneration, perhaps not so exaggerated as seen in the specimen presented.

CEREBRAL MENINGITIS.

Dr. PEABODY presented a brain with the following history: A. C—, forty-three years of age, a native of the United States, and a widow; no occupation. She had had alopecia, pharyngitis, iritis, and indefinite pains, but no rash or initial lesion, or glandular enlargements or scars. Her tibiae were nodular when she came under observation. She had rheumatism four years ago, and had since experienced vertigo and tinnitus aurium, but had had no œdema, no palpitation of the heart or other indication of involvement of that organ. On December 4th, at night, she had a severe chill, followed by high fever, headache, photophobia, and a feeling of general soreness all over the body. On the following day she began to suffer from nausea and vomiting, which have continued steadily up to the time of her admission to the New York Hospital on December 7th. At the same time with the development of these gastric symptoms her left wrist became very tender, swollen, hot, and stiff. No other joint was affected, but she had severe pain in the lumbar and inguinal regions, together with pain in the popliteal spaces, and in the calves of the legs. There was no special spinal or cervical tenderness, but there was some stiffness of the neck. On the day after the chill she became quite deaf, and continued so. On admission she was well-nourished, and presented a number of suggestive symptoms. Her left pupil was slightly larger than the right, and there was slight left exophthalmus. Her left wrist was swollen, stiff, hot, and painful. Its color was normal. No lesion of the thoracic or abdominal viscera was detected. Her temperature was 102° F.; her respirations were 20, and her pulse was 78. She was unable to pass water. She was then given ext. ergot, f 3 j. q. 3 hours, and also morphine per os to relieve her pain.

December 8th.—At 9 A.M.: Temperature, 102.5° F.; respiration, 26, and pulse, 80. 12 M.: Temperature, 102.6° F. 5 P.M.: Temperature, 101.6° F.; respiration, 28, and pulse, 70. Slight herpetic eruption on upper lip

Slight facial contortions noted. Patient has relapsed into a semi-comatose state and can hardly be made to take medicine.

December 9th.—No rash; herpes spreading; no joint symptoms; stupor deepening; cardiac action excellent. 9 A.M.: Temperature, 102.4° F.; respiration, 26, and pulse, 80.

December 10th.—Temperature yesterday in P.M. was not above 102.8° F. This A.M. temperature, 102.8° F.; respiration, 36, and pulse, 80. Respiration labored; stupor complete. Patient cannot be roused and medicine is given with difficulty. During the past three days a rapidly developing keratitis has invaded both eyes and has now become intense. It has been treated by atropia locally in solution. Was given whiskey ʒ ij. last night. Still no muscular twitchings or joint symptoms; no rash. 5.30 P.M.: Temperature, 102.9° F.

December 11th.—10 A.M.: Temperature, 102.9° F.; respiration, 36, and pulse, 90. She is now comatose. Pulse growing feeble. Ordered whiskey, ʒ iv. in the day and ʒ iij. in the night. No change in symptoms. Keratitis worse, inflammation intense. Herpetic eruption involves most of the upper lip. Still swallows.

December 12th.—Patient completely comatose. Heart's action growing more feeble. Pulmonary œdema developing. Ordered ether, ʒ ij. (hypodermically), q. three hours and enemata of whiskey, ʒ j. Ammon. carbonat, gr. x. (given twice). Intravenous injection of aq. ammon. and digitalin hypodermically. Heart's action fairly sustained, but temperature slowly rose. 11 A.M.: Temperature, 102.8° F. 2 P.M.: Temperature, 103.2° F. 6 P.M.: Temperature, 104.6° F. 10 P.M.: Temperature, 105° F. Pulmonary œdema increased. Heart finally failed, and at 3.15 A.M., December 13th, she died (temperature, 107.4° F.).

The autopsy was made a few hours after death. The only organ of interest was the brain. The pia was intensely congested and there was a large amount of pus in the cross meshes of the pia at the base, and extending thence into the fissures of Sylvius. The lateral ventricles contained also much thick pus, chiefly in the meshes of the choroid plexuses. Inasmuch as rheumatic symptoms occurred a few hours after the initial chill, in this case the question had arisen, Might this be considered a case of rheumatic meningitis?

The Society then went into executive session.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, January 4, 1883.

FORDYCE BARKER, M.D., LL.D., PRESIDENT, IN THE CHAIR.

Dr. F. H. BOSWORTH read a paper (see page 29) on

GROWTHS IN THE NASAL PASSAGES.

Being called upon by the President to open the discussion, Dr. LEFFERTS said that to a number, perhaps the majority, of points made by Dr. Bosworth in his paper, no exception could be taken. They were such as were well understood and adopted by all specialists. Others, however, were open to question. Some must be controverted. The latter two classes alone needed discussion. First, as to adenoid vegetations, the profession, the lecturer tells us, believes them to be rare. This can hardly apply to its reading members, for the subject has of late been treated of in journals and monographs *ad nauseam*. He believes them to be exceedingly common—the most frequent of the many conditions which give rise to an abnormal discharge from the nose—and his statistics and the wonderful array of specimens upon the desk seemed to prove his assertion; but the truth, according to Dr. Lefferts' experience, lay between the two extremes. We must be careful not to confound simple irregularities of the tissue at the pharyngeal vault, hardly to be called abnormalities, especially in the young subject, with true

hypertrophies deserving of the name. Excessive hypertrophy, giving rise to veritable tumor and to all the symptoms so graphically described by the author of the paper, are not very common. Moderate hypertrophy is frequently met with in the catarrhs seen in young children, but still in a large proportion of them it does not exist. He had not met with it in anything like the frequency indicated by Dr. Bosworth, even in children. In the adult he believed it to be a very rare manifestation; and here a practical point arose, bearing in mind the fact—one not always appreciated, even if recognized by specialists—that these growths disappear, as a rule, with the advent of puberty. Is it always necessary to interfere with them by operative, and, in children, often formidable means, simply because they do exist? He believed not, referring, of course, to cases where the grade of the hypertrophy was moderate. If excessive and giving rise to both local and general disturbances, operative measures were indicated, nay, demanded, beyond question. In these days he did not fear that not enough would be done. He deprecated the tendency to do too much, and to rather over- than under-estimate the significance of the disease.

As to the means of treatment, Dr. Bosworth was a warm advocate, as was shown in his recent writings, of the "Jarvis" snare, an excellent modification and adaptation of some pre-existing forms of apparatus. There was no question as to its value in many varieties of nasal disease, especially hypertrophies, but it demanded, notably in the naso-pharyngeal space, much manual dexterity, and hence was not of general applicability. Certainly it was not generally recommended nor used by the special operators of to-day. Perhaps it ought to be. A new model of a biting forceps lately introduced had in his hands answered an excellent purpose. It was warmly recommended by operators of large experience abroad. It could be used even by those without special training, and in cases in young children where the adjustment of the wire snare would be a matter of great difficulty, if not impossibility. As to the use of the galvano-cautery for destroying these growths, he would only ask his hearers to try it once in young children, and thus purchase their experience with discomfort, danger, and difficulty. In advising a method of treatment it was of great importance to select one both practical and practicable.

Time did not permit him, as he would like to do, to criticise some of Dr. Bosworth's statements in regard to nasal polypi-myxomatous growths. One point only: Did not the frequency with which he had met with these tumors depend partly upon the fact that he had diagnosed and removed some, in a state, if he had rightly understood his expression, of rudimentary development? The title of the paper, "Tumors of the Nasal Passages," permitted him to call attention to two forms of growths not mentioned by Dr. Bosworth, viz.: cystic growths, and papillomata. The former are rare, it is true, but possess a practical interest from an operative point of view; they resemble exactly the ordinary gelatinous polypus; but seized by forceps or otherwise burst, discharge their contents, and the sac alone is torn away; the operator believes this to be but a portion of the tumor, and renews his efforts now to remove the remainder of what does not exist. Laceration of normal structures is the result. He willingly, therefore, endorsed the practical suggestion of Dr. Bosworth, always to *look* and work carefully when removing a nasal growth; by not so doing he himself had made the mistake alluded to.

The second form of tumor, the papilloma, is not uncommon, and gives rise to persistent, often, apparently, unexplainable epistaxis. This fact alone shows the importance of its recognition; it is readily seen in its usual location upon the nasal septum, far down toward the orifice of the nostril, and is as readily removed by clipping with scissors and cauterization of its base.

Finally, notwithstanding Dr. Bosworth's poetical illus-

tration, used in support of his position, that nasal disease is the cause of the change in the upper register of the singer's voice, and that the latter is the first to become affected, as the voice shows signs of impairment, he must take exception to the statement. The middle register, experience shows, he thought, was the one to become first affected; if this were so, the theory built up by Dr. Bosworth was overthrown, it not wholly, at least in part. This subject was, however, a large one, and could not now be entered upon, especially as he had consumed already so much valuable time, for which trespass he apologized, and pleaded in excuse the interest of the subject, so well treated of by Dr. Bosworth.

DR. R. C. BRANDEIS thought that with either inflammation of the pharyngeal tonsil, or the existence of the adenoid growths, there must be some inflammation of the adjacent structure, and further, that the inflammation was as liable to extend upward into the Eustachian tube as downward into the pharynx. He, therefore, believed that impairment of hearing, in these cases, was due largely to obstruction of the Eustachian tube produced by the congested or swollen mucous membrane. In consequence of such obstruction the air was removed from the cavity of the middle ear, thus permitting pressure upon the external drumhead to produce distortion of that membrane. If the orifice of the Eustachian tube was only temporarily congested, its walls were brought into contact with each other, the air in the cavity was gradually absorbed, and impaired hearing was the result of malposition of the drum.

With regard to the use of the galvano-cautery in the naso-pharyngeal space, he had not met with any evil consequences in resorting to it. He had adopted it frequently for the removal of nasal polypi, and believed that in those cases it subserved a double purpose, namely, it acted as an *écraseur* and at the same time as a caustic. He regarded it as necessary to destroy the roots of nasal polypi entirely, if the liability to their return was to be entirely obviated.

DR. R. P. LINCOLN thought it was generally conceded that there were many tumors in the nasal passages which were dangerous to the patient, and that the harm which they produced was far-reaching. With regard to the necessity of operation for the removal of growths in the post-nasal region, particularly of adenoid tissue, it seemed to him that it depended entirely upon the fact as to whether they were the source of any impairment of health or produced any special discomfort. The necessity for the removal of these growths might be alone the discharge which they produced, because that discharge of itself caused harm, not only in the pharynx, but as he believed, also in the stomach, giving rise to indigestion. Besides, they might produce a reflex influence upon distant parts, as had already been mentioned by Dr. Bosworth, and might give rise to asthma. It was also astonishing how small a growth would produce asthmatic symptoms. Another evil effect due to obstruction of nasal breathing was a malformation produced in children while they were quite young; that is, previous to six, eight, or nine years of age. He had seen a number of cases in which it seemed to him that no other explanation could be given for the malformation of the chest, than that it was consequent upon the difficulty of breathing through the nose. He believed it was a practical point with which every medical man should be made familiar.

With reference to treatment, he took issue with Dr. Bosworth's statement that "all other methods than the use of the wire *écraseur* were inadequate." He had employed the galvano-cautery and also chromic acid with very satisfactory results, and had published quite a large series of such cases in which these methods of treatment had been adopted. He thought also there were other remedies which could be used advantageously for the same purpose. For example, the Vienna paste had been and could be used with success for the removal of enlarged tonsils and also for the removal of the growths

under consideration. Jarvis' snare-écraseur, however, was certainly a most valuable instrument. He himself used it more than any other instrument, both in the anterior and posterior nares. He did not believe that anything else could be devised which would replace it. There were, however, other remedies which would accomplish perfectly satisfactory results, especially when the fact was taken into consideration that most of the growths in the posterior cavity of the nares disappear after puberty. A remedy which he had recently used, and one to which he wished to direct special attention, was boracic acid, especially where the growth was small and yet gave rise to a profuse, annoying discharge. This remedy might be used, finely powdered, pure or diluted with subcarbonate of bismuth, and by the aid of one of the many powder-blowers.

DR. B. ROBINSON remarked that while it was true most were familiar with Jarvis' snare-écraseur, and perhaps we had been led chiefly to use it from the fact that it had been so strongly recommended by Dr. Bosworth, yet the fact remained that it was not the only instrument which could be made use of in destroying these growths. It was, however, probably the best. In cases in which the growth was of some size he thought it was decidedly the best instrument which could be employed. Where the growths were small, flat, and sessile, and did not cause any distressing symptoms, he thought the galvanocautery or some methods of removal by scraping could be used satisfactorily. But for removal of the growths of the size exhibited by Dr. Bosworth, certainly the Jarvis wire-écraseur was the best instrument which could be employed.

There was one point which he believed had not been sufficiently impressed, and that was the continued sucking out of the breast, so to speak, when the nasal passages were obstructed, and this was true without reference to what the cause of the obstruction was, provided the obstruction took place in the anterior part of the nasal passages.

Personally, he believed that there was such a thing as propagation of the catarrhal inflammatory condition directly from the affected parts to the Eustachian tubes, and in that way to the middle ear. To such an extension of the inflammatory process he attributed many of the cases of impaired hearing.

DR. BOSWORTH, in closing the discussion, said, with reference to the question as to whether or not we should operate when there was only a moderately large adenoid growth present, that doubtless many of the growths atrophied at about the age of puberty. But that period might be at some distance, and the child might be suffering from certain symptoms which should be relieved. The tendency in many of these cases was to produce sleepless nights, weak throats, impeded respiration, etc., and he believed it to be the duty of the surgeon to relieve the patient of such symptoms, even if he felt certain that the growth would atrophy within a few months or within a year. Furthermore, we were not absolutely certain that they would disappear.

With regard to the use of the forceps and the snare, he thought that the forceps could not be made to reach the entire growth on account of its peculiar anatomical situation. He had never seen a pair of forceps with which the entire growth could be reached.

With reference to the register of the singing voice first affected, his conclusion was that it was the upper register which was first involved had been based largely upon the statement made by singers themselves.

With regard to the extension of catarrhal disease through the Eustachian tube, he thought it was a good point, but, at the same time, in the examination of a very large number of cases he had rarely seen evidence of catarrhal inflammation at the trumpet-shaped extremity of the Eustachian tube; that is, there had been neither swelling nor redness, nor had there been evidence of pain or heat.

With reference to impairment of hearing, he believed that the levator palati muscles played an important part in the admission of air into the middle ear, and that the adenoid growths in the vault of the pharynx interfered with the proper performance of their function. The inference was that the growths should be removed.

The Academy then adjourned.

SECTION IN PRACTICE.

Stated Meeting, December 19, 1882.

ANDREW H. SMITH, M.D., CHAIRMAN.

THE COMPLICATIONS, SEQUELÆ, AND TREATMENT OF SCARLET FEVER.

DR. J. LEWIS SMITH read a paper on the above subject, in which he directed attention first to *the complications affecting the nervous system*. These were of two varieties: 1, those which developed during the early days of the disease, and 2, those which appeared in the declining stage, when they occurred from uræmia chiefly. The occurrence of delirium or convulsions during the first days generally indicated the presence of a sufficiently severe type of the disease to prove fatal speedily. The prognosis, however, in such cases was much more favorable than in former times, and the improvement was due to our better understanding of the application and the effects of agents employed for the relief of certain symptoms, such as high temperature, as well as for the control of the complication itself. The use of cold was recommended for the control of the temperature, applied in the form of sponging, or the pack, or the full bath, whenever the thermometer registered above 103° F. For the convulsions, bromide of potassium could be administered with impunity in large doses repeated frequently, and if it failed, the use of hydrate of chloral by the rectum would almost surely prove successful. Use a small glass syringe, and to children from one to three years of age five grains of chloral dissolved in two drachms of water could be given.

SEVERE PHARYNGITIS, CERVICAL CELLULITIS, AND ADENITIS.

Dr. Smith had never met with a case of scarlet fever in which there was not evidence of pharyngitis before the appearance of efflorescence upon the skin. Pharyngitis, therefore, was not regarded as a complication unless it attained that degree of severity in which the inflammation extended into the tissues of the neck and produced destructive tissue change. There were two forms which occurred as complications: 1, an aggravation and extension of the inflammatory process always present, and 2, true diphtheria. The first usually becomes considerable, if it is to exist as a complication, at about the close of the first week, sometimes within the first two days. In some cases the tumefaction is so great that the mouth can be opened only with very great difficulty. In mild cases resolution occurs; in the severer ones ulceration, possibly gangrene.

DIPHTHERIA

occurred frequently as a complication of scarlet fever. In localities where the former disease prevailed, from one-third to one-half of the cases of scarlet fever became complicated with diphtheria, without the probability of an exposure to the poison of the latter disease, or to the influence of sewer-gas. The complication had occurred so frequently in his practice that Dr. Smith had come to regard scarlet fever itself as a cause of diphtheria in a locality where diphtheria prevails. The reverse, however, he did not think was true. Usually, the complication did not appear until the third or fourth day, but sometimes it began almost simultaneously with the scarlet fever.

OTITIS MEDIA,

as a complication of scarlet fever, was attributable to extension of the inflammation along the Eustachian tube from the naso-pharyngeal surfaces.

SCARLATINOUS RHEUMATISM.

This usually commenced at the close of the first or the beginning of the second week, and commonly affected the wrists and ankles. It did not seem to retard convalescence, but its chief danger was the liability to cardiac complication.

PERICARDITIS

occurred as a complication more frequently, probably, than was generally supposed.

PLEURISY

was one of the most important complications. It developed usually in the desquamative stage and was apt to be suppurative.

DILATATION OF THE HEART,

coincident with quick feeble pulse. At autopsies firm whitish clots were found closely adherent to the columnæ carneæ, and extending into the large vessels.

NEPHRITIS.

In a mild form it occurred according to his observation much more frequently than had been formerly supposed. Renal catarrh might occur without urinary evidence. Special reference was made to Steiner's cases. The complication usually began in the desquamative stage, and Dr. Smith believed that exposure to cold was one of the causes. According to Klein a tubal or parenchymatous nephritis occurred early, and after about nine days interstitial nephritis existed. Reference was also made to the glomerulo-nephritis described by Klebs, and to the criticisms made by Klein, who did not accept Klebs' views upon this point. With reference to

PROPHYLACTIC TREATMENT,

he thought there was no remedy which could prevent the spread of the disease. Concerning the use of water, cold or lukewarm, with sponge, pack, or bath, Dr. Smith remarked that he regarded it as one of the most valuable agents that could be employed for reducing temperature and affording general relief to the patient. Inunction was serviceable, especially in the desquamative stage, and with such substances as vaseline or carbolized applications. On the use of water, Dr. Smith also read Hensch's views, recently published in German.

DR. L. WEBER thought, that the scarlet fever poison never produced true diphtheria, and that when the two affections existed in the same patient it was a coincidence. He believed that the condition of the mucous membrane of the throat in scarlet fever might be such as to induce the invasion of diphtheria. He was of the opinion that Hensch, just quoted by Dr. Smith, believed that these two diseases might co-exist in the same person, but that scarlet fever never caused diphtheria.

Dr. Weber had seen erosion of the jugular vein as the result of suppuration of cellular tissue and adenitis in scarlet fever.

DR. E. G. JANEWAY recalled a case which illustrated how mistakes were sometimes made. The child was said to have syphilis from vaccination because there was enlargement of the cervical glands. The complete history of the case proved it to be one of undoubted scarlet fever, and the practitioner who made the statement concerning syphilis had hit upon the time when there was enlargement of the cervical glands without efflorescence of the skin, and besides the child had been vaccinated. Again, when scarlet fever prevailed attacks of sore throat were frequent among children. Such cases, when observed independent of scarlet fever, would usually be called follicular faucitis. Yet it was probable that many of them

continued the spread of the disease. He had seen purulent inflammation of joints instead of the ordinary rheumatic inflammation in several cases.

ORIGIN OF HEART-CLOTS.

With reference to clots in the heart, spoken of by Dr. Smith in connection with dilatation of the heart, firm, whitish, usually entangled somewhat in the chordæ tendineæ, and often regarded as ante-mortem, he had doubts about their being of that character. The mechanical conditions were very much the same as that obtained when blood was placed in a vessel and allowed to coagulate; the buffy coat formed at the surface and the dark blood sank to the bottom; so when the circulatory organs were in position the buffy coat formed in the heart and the dark blood sank into the pulmonary artery. Still further, a man in his wards in Bellevue Hospital had symptoms which led him to suppose that the right heart was overloaded with blood. Feeling that benefit might follow the withdrawal of blood from the overloaded heart cavity he introduced a hypodermic syringe and removed a certain quantity. That which was drawn off was pure fluid black blood. The heart had ceased beating before the syringe was introduced, and the withdrawal of the blood was not followed by cardiac action. Dr. Janeway then injected a solution of carbonate of ammonia into the same cavity, but it also failed to excite the heart to action. At the autopsy there was found a firm white clot entangled in the chordæ tendineæ and the columnæ carneæ and *not any* dark fluid. Immediately after the heart ceased beating the right cavity contained fluid black blood; at the autopsy there was no fluid black blood in the same cavity, but a firm white clot, entangled in the muscular and tendinous structures. The case, therefore, seemed to prove conclusively that, in some cases at least, the white, and particularly the whitish, clots found in the heart at autopsies were not ante-mortem.

With reference to *prophylaxis*, Dr. Janeway believed that there were exceptions to the general belief that within the first few hours of scarlet fever no danger from contagion existed. Again, the latter part of the desquamative stage seemed not to be contagious in some cases. There was no definite rule that could be laid down. As a matter of safety advantage should be taken of all precautionary measures. Inunction during the desquamative stage was beneficial and should be adopted.

DR. C. E. BILLINGTON believed that the co-existence of scarlet fever and diphtheria was very common, but he thought that the condition of the throat in scarlet fever favored the accession of diphtheria. He had frequently seen cases, regarded as diphtheria, which had developed upon the sore throat accompanying scarlet fever. One evidence that the cases were primarily scarlet fever was the occurrence of otitis media, which rarely developed in connection with simple cases of diphtheria. He regarded inunction as very valuable in scarlet fever.

DR. J. C. PETERS always directed attention to the throat, the kidneys and the skin in all cases of scarlet fever. He believed that the so-called period of incubation was merely the working of the poison through the mucous membrane of the throat. When it had found its way through, and entered the blood, the symptoms at once began to develop. He believed that the blood was unaffected during the six or eight days of incubation, and therefore directed especial attention to the throat. Of course, he had not prevented the disease in that way, but he thought he had modified its course. With reference to the skin, inunction was very serviceable. The kidneys should receive early attention. He accepted the view that desquamation occurred in the uriniferous tubules, the same as upon the external surface of the body, and that it did not necessarily lead to nephritis. Sweet spirits of nitre and syrup of tolu was a favorite combination with him. Besides the inunction he used tepid baths, the temperature of the water never being less than 90° F. He had been afraid to use cold baths.

DR. BURRALL spoke of the use of antiseptic applications to the throat.

DR. A. S. HUNTER favored simply wetting the surface with warm water, and then exposing it to the air, as a means for reducing temperature.

DR. PUTZEL believed that the frequent co-existence of scarlet fever and diphtheria mentioned was an exception to the rule concerning infectious diseases, because it was exceedingly rare for two infectious diseases to run their course in the same person at the same time. He thought that the mistake had occurred, perhaps, in confounding anatomical diphtheria with clinical diphtheria. The occurrence of a diphtheritic exudation upon mucous surfaces did not necessarily indicate the presence of true diphtheria.

THE CHAIRMAN directed attention to marked dyspnoea as a complication, without apparent obstruction to either the respiration or the circulation. It seemed to be due to the effect which the poison produced upon the blood-corpuscles, rendering them unable to perform their function as oxygen-carriers.

DR. JANEWAY remarked that these cases of dyspnoea had been described under the head of uræmic dyspnoea. With reference to the co-existence of scarlet fever and diphtheria, the decision turned largely upon the answers to be given to the question. What is clinical and what is anatomical diphtheria? That anatomical diphtheria—that is, a false membrane upon the surface and invading the substance of mucous membranes—could occur without true diphtheria, he believed to be well established.

DR. J. LEWIS SMITH, in closing the discussion, referred to the difficulty in making a differential diagnosis, especially in cases of scarlatina anginosa, where there was destructive inflammation of the mucous membrane in the throat. Still he believed that the two diseases did occur undoubtedly in the same patient at the same time. Of course, such cases were somewhat rare, but of their existence he had become fully convinced. At the same time, he did not suppose the co-existence would be seen where diphtheria did not exist. He would be pleased to receive information upon this point from rural practitioners who had had to deal with the two diseases. He thought that one of the avenues by which the poison of scarlet fever gained admittance to the system was through the lungs; that the access was by no means confined to the throat.

The Section then adjourned.

THE PROGNOSIS OF IDIOCY.—The late Dr. E. Seguin, who was the highest authority, although somewhat over-sanguine, said regarding the results of attempting to train idiots: Not one in a thousand has been entirely refractory to treatment; not one in a hundred who has not been made happy and healthy; more than thirty per cent. have been taught to conform to social and moral law, and rendered capable of order, of good feeling, and of working like the third of a man; more than forty per cent. have been capable of the ordinary transactions of life under friendly control, of understanding moral and social abstractions, of working like two-thirds of a man; and twenty-five per cent. come nearer and nearer to the standard of manhood, till some of them will defy the scrutiny of good judges when compared with ordinary young women and men.

THE GOSPEL OF FATNESS.—Dr. Clouston, of Edinburgh, says: "All acute mental diseases, like most nervous diseases, tend to thinness of body, and therefore all foods and all medicines and all treatments that fatten are good. To my assistants and nurses and patients I preach the gospel of fatness as the great antidote to the exhausting tendencies of the disease we have to treat, and it would be well if all people of nervous constitution would obey this gospel."

Correspondence.

ON THE STRENGTH OF OPIUM.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR: In your valued journal of December 9th, reference is made to an article contained in Dr. Squibbs' *Ephemeris*, of November, 1882, and some remarks are appended in regard to the "inexcusable oversight in the Pharmacopœia Committee," which call for an answer, as both the *Ephemeris* article and your comments are at fault.

Dr. Squibbs compares the *lowest* percentage of morphine strength of opium permitted by the last Pharmacopœia with the *average* percentage allowed by the new, an evidently unfair comparison. It would have been fairer to compare the *lowest* percentage allowed by both Pharmacopœias. The assay process of opium of 1870, in average hands, gave poor results, so that an opium which assayed ten per cent. was more nearly twelve per cent. in actual strength, and, therefore, nearly identical with twelve per cent. opium as assayed by the present superior processes. But the Pharmacopœia of 1870 did not require opium to be of ten per cent. strength, but "*not less than ten per cent.*," clearly making opium of sixteen per cent. or more come within its provisions. There simply was no upper limit to the strength. Little of the opium in the market contains only ten per cent. of morphine without being of so poor a quality as to be rejected for pharmaceutical uses on account of its appearance alone, and such an opium is but just strong enough to pass the inspection of the United States Customs Drug Examiners.

The *average* strength of fair specimens of opium to be obtained in the market has always been far above the lowest grade permitted by the old Pharmacopœia, and it is safe to say that this *average* strength has been about thirteen or fourteen per cent. for many years past. Dr. Squibbs himself has all along aimed to furnish an opium of thirteen and one-half per cent. strength, and has stated that he would not sell any of less than twelve and one-half per cent. strength, which would be from twenty-five to thirty-three per cent. higher than the grade with which he now compares the standard of the new Pharmacopœia. If, therefore, a physician prescribed opium, and Dr. Squibbs' opium was dispensed, the patient received a twenty-five to thirty-three per cent. stronger article than designed, thus exposing the patient to the dangers now pointed out in the article in *Ephemeris*, or rather, he would have been so exposed, if the *average* grade of all opium had not been fully up to Dr. Squibbs' opium.

The statement that "of course, a pound bottle of the new preparations will be equal to a pound and a half of the old" is wrong. The market is a sensitive thermometer of the actual value of opium preparations, and while a rise in cost may occur, due to fluctuations in opium value, we dare predict that no marked rise will occur on the ground of variation in the pharmacopœial standard. In other words, the strength of opium is not changed by the present Pharmacopœia, but the *description* of opium has been simply made to correspond to the actual trade conditions.

The opium the physician will hereafter use will be practically the same as that which he has heretofore employed, while a few of the preparations have been slightly raised in strength, but not sufficiently so to affect the doses.

Besides, as a matter of fact, and regardless of the question of propriety or impropriety, it may be stated that physicians do not prescribe opium, grading their dose with reference to any particular opium strength, and least of all do they base their dose upon a uniform strength of ten per cent. Nor is it necessary that they should so calculate, because they know that the average

opium that is apt to be dispensed on their prescriptions will have an average effect to which they are accustomed. It is therefore probable that the change to which attention has been called is altogether confined to the pages of the *Pharmacopœia*, and that physicians will go on prescribing opium just as heretofore, and will obtain the same effects.

Very truly yours,

O. A. WALL, M.D.

St. Louis, Mo.

TRACHEOTOMY IN YOUNG CHILDREN.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR: Your report of a successful tracheotomy in a child only eleven months old stimulates me to furnish you, for the benefit of those who may be interested in gathering statistics in the future, the histories of two little patients, each twenty-two months old, who developed laryngeal complications during diphtheria. That the affection was genuine diphtheria was proven by the sequel to each, namely, paralysis of several muscles, such as the eye and also of the throat and pharynx. These two cases were in the practice of my associate, Dr. A. J. Dower. I assisted at the second operation, and also saw patient during his subsequent treatment.

CASE I.—Charles F——, aged twenty-two months. He had been sick about four or five days before Dr. Dower saw him.

On his first visit he found marked diphtheritic infiltration of pharynx, tonsils, etc. In addition he had infiltrated cervical glands. In two days from when first seen laryngeal obstruction began. This was doubtless due to the usual manner, of extension of inflammation to larynx.

After this condition of things had lasted for forty-eight hours nearly, and was increasing, Dr. Wallace was called in consultation. It was decided, after examination, that it would be well to still wait and continue same treatment. As there was no improvement, tracheotomy was performed. The asphyxiated state, as manifested by generally engorged condition of veins and contraction of inferior portions of chest with supra-clavicular depressions, was immediately relieved thereby.

Assisting the doctor at this operation were Drs. Jarvis, Wright, and McCorkle.

With the exception of three days, convalescence was immediately established. Only moderate amount of bronchitis ensued from operation. Paralytic manifestations occurred as sequelæ to this disease as usual. Unilateral strabismus as well as paralysis of soft palate and epiglottis. It was attempted to remove tube on the seventh day, but dyspnoea ensued as soon as it was removed and so it was left to the tenth day. Wound gradually closed in and was healed soon.

CASE II.—Andrew J. F——, aged twenty-two months. He was sick six days before the tracheotomy was performed with marked infiltration of tonsils and pharynx. Gradually laryngeal inflammation and stridor set in.

Preceding the laryngeal stricture he had had the usual anti-diphtheritic treatments. The laryngeal obstruction increased, as manifested by the rarefaction of air in the chest, by supra-clavicular depressions during inspiration, as well as the same condition over the inferior portion of the chest, and a general venous obstruction, as manifested by blue prolabia, etc. Coma increased. Operation of tracheotomy done with immediate relief to asphyxia. Subsequently the progress of case was not interfered with and good recovery ensued. Had paralysis after operation of the soft palate and uvula, allowing milk and medicine to enter the larynx and emerge by tracheal tube. This lasted a few days, and later in convalescence he had facial paralysis. Only moderate amount of bronchitis followed tracheotomy.

Blackwell's Island.

ON THE REMOVAL OF FOREIGN BODIES FROM THE EAR.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR: When recommending my aural foreign-body forceps in a communication published in *THE MEDICAL RECORD* of December 23, 1882, I certainly did not expect its employment would meet with the vehement opposition which is shown in Dr. Knapp's letter in *THE MEDICAL RECORD* of January 6, 1883, especially as the writer thereof seems never to have given it a trial. It was scarcely necessary for Dr. Knapp to draw our attention to the French and German devices of the past fifty years, for the removal of foreign bodies, inasmuch as the extensive circulation given by Wood's Library of Standard Authors to Poulet's "Foreign Bodies in Surgery" places a very exhaustive list before the profession. The real question is, not the removal of foreign bodies as found by the expert just as introduced by the child, but it is, how shall they be treated when deeply impacted? It is in such cases that one often finds the parts lacerated by previous efforts at removal, the swollen walls of the external auditory canal so closely embracing the foreign body that neither hooks or spoons can be easily or safely passed; a state of things, in fact, which a careful perusal of Dr. Knapp's letter does not convey the idea that he has as yet encountered. When the deeply impacted foreign body completely obstructs the canal, as is often the case, the operator, after forcing his instrument beyond it, finds himself working in the dark and unable to operate skilfully; he cannot determine how near the foreign body lies to the drum-membrane, and when it is situated very near to that delicate structure no one possesses the requisite delicacy of touch to always avoid its laceration—an injury the consequences of which are inflammation of the middle ear and its attendant evils. And it should be borne in mind just here that no serious result need be usually apprehended from the presence of a foreign body in the canal of the ear unless it be pushed down upon the drum-membrane, or into the middle ear, thus injuring these parts, or unless the middle ear be injured by poking instruments behind the object. Should the instrument which Dr. Knapp, in his letter, proposes to have made so as to open its prongs when thrust back behind a foreign body, ever be made and brought into use in these difficult cases, one can scarcely foretell the destruction such a device would be capable of doing, even in his skilful hands. In regard to the seemingly disparaging quotation made by Dr. Knapp from *The American Journal of Otology*, it may appear to be an ingenuous argument to those who have not access to the files of that journal against the efficiency of my forceps; but the extract is garbled and disingenuous, for Dr. Joy expressly states, in referring to the first attempt to remove the locust-bean before it became disintegrated by maceration in the secretions surrounding it in the canal: "I am positive that if we could have used these forceps (referring to Dr. Sexton's) in the first operation, the bean would have been removed in its entirety." And Dr. Joy reports, in the same article, another case where an impacted brass mounted glass-stud was removed with these forceps after other kinds had been unsuccessfully tried.

The former case was referred to as the one which suggested the construction of the forceps which has been subsequently used so successfully in a large number of similar cases.

In conclusion, it may be stated that the forceps here alluded to by me will not only grasp such beans as shown in the cut which accompanied my letter in *THE MEDICAL RECORD* of December 23, 1882, without necessarily pushing it farther in, but it will also retain its hold while very great traction is made.

With means of this kind at hand—which are also ap-

plicable to the extraction of foreign bodies from the nose—I shall, until something better is found, prefer to operate in these cases by seizing the presenting portion of the object, and thus exert tractive force, to adopting the plan offered by Dr. Knapp, which consists in applying a pushing power from behind. Yours sincerely,
SAMUEL SEXTON, M.D.

Army and Navy News.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from December 30, 1882, to January 6, 1883.

McKEE, J. C., Surgeon. To report on or before January 1, 1883, to the Commanding Officer, Fort Winfield Scott, California, for assignment to duty as Post Surgeon. S. O. 197, par. 1, Department of California, December 28, 1882.

GORGAS, W. C., Assistant Surgeon. Relieved from the temporary duty to which assigned under S. O. 137, par. 4, Department of Texas, and will report to the commanding officer, Fort Brown, Texas. S. O. 140, par. 2, Department of Texas, December 26, 1882.

Official List of Changes in the Medical Corps of the Navy for the week ending January 6, 1883.

TIBBS, HENRY B., Assistant-Surgeon. Ordered to the U. S. S. Jamestown.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Comparative statement of cases of contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending January 6, 1883:

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
December 30, 1882	0	13	45	6	40	35	0	0
January 6, 1883	0	6	64	10	46	52	0	0

THE MANAGEMENT OF THE TEXAS EPIDEMIC.—Dr. J. B. Hamilton, Surgeon-General U. S. Marine Hospital Service, writes, regarding the Texas yellow-fever epidemic: "You were mistaken about the United States not quarantining the Rio Grande between Laredo and Brownsville, though it did not quarantine in Mexico, as has been charged. Please correct this point, as the safety of Texas is due, we think, to that *cordon*. The Mexicans, after they saw the good effects of quarantine in Texas, adopted similar means of arresting the disease on their side and with success."

A NEW USE FOR THE CONDOM.—Dr. J. Newell Robertson of Walcott, N. Y., writes: "F. A. came to my office on the evening of December 6th with a piece of bone in the lower fourth of the œsophagus which lodged there the evening before while eating a 'boiled dinner.' I introduced several sizes of flexible catheters, could feel the substance distinctly, and succeeded in pushing it down about one inch. I then fastened a piece of tissue rubber to the end of a catheter, passed it below the sub-

stance, inflated it, then withdrew it, doing it several times. I then, at the suggestion of Dr. Wilson, employed a condom in the same way. Failing as with the first, I inflated it *above* the substance, pushing it gently down, and found to my satisfaction that the 'bone of contention' passed easily before it."

SHAKESPEARE ON DEATH.—Of the deaths by poisoning two are minutely described. One takes place off the stage, and is only named to us; two are sudden—the Queen in "Hamlet," and Romeo. In these last cases the agent was clearly hydrocyanic acid in some form, a vegetable extract, such as laurel-water, killing almost at once, and painlessly, leaving no time for thought, but only for the certainty of quick-coming death. King John, on the other hand, is poisoned by a corrosive irritant, probably mineral, comparatively slow in its action, of which burning heat is the chief symptom:

"There is so hot a Summer in my bosom,
That all my bowels crumble up to dust.
Against this fire
Do I shrink up?
None of you will bid the Winter come,
To thrust his icy fingers in my maw,
Nor let my kingdom's rivers take their course
Through my burned bosom, nor entreat the North
To make his bleak winds kiss my parched lips?"

The elder Hamlet, again, dies by vegetable poisoning. There is a strong reason for thinking that the true reading of the drug is not the usual "hebenon," but "hebona," or yew juice, for the symptoms are precisely those caused by this, and by no other. Whether, in the then state of anatomy, Shakespeare really believed, contrary to the truth, that such a juice poured into the ear would so course through the body, is not clear. It is probable that he took the old story, so far as he needed to do so, but having made it responsible for the mode in which the foreign element was introduced into Hamlet's frame, used then his own observation and curious plant-lore for the efforts which the body made to cast it out. The many cases of death by steel are very closely studied from nature. Those who have carefully examined the dead on a battle-field, or in the streets after an émeute, are struck with the fact that while the expression on the faces of those who have died by gunshot wounds is one of agony and distress, the dead by sword have a calmer expression, though their wounds often seem more painful to the eye. A very careful observer, who was through the Indian mutiny, entirely confirms this. After giving several instances, he says: "A rapid death by steel is almost painless. Sabre edge or point divides the nerves so quickly as to give little pain. A bullet lacerates." This is in entire accordance with Shakespeare's diagnosis. York, in "Henry IV.," dies "smiling"; so young Talbot, in 1 "Henry VI.," "Poor boy! he smiles." In the great majority of cases there appears to have been no acute pain; and such distressful sensations as were felt, when there was time to feel anything, were those of cold. Death, therefore, resulted from hemorrhage, of which an exceeding chilliness, without pain, is always the consequence. Hotspur and Warwick both speak of this chill, "the earthly and cold hand of death," the "cold, congealed blood." The only instances in which acute pain wrung "groans" from the sufferer were those in which death was long delayed, when, as with Clifford, "the air has got into my deadly wounds," and Montague also groans from the delay. There is a most striking passage in Jeremy Taylor's sermons in which he speaks of wounds to the same effect, but attributes the painlessness of a wound at first, wrongly as it would seem, only to the heat and rage of the fighter, who has no time to feel. "I have known a bold trooper fight in the confusion of a battle, and, being warm with heat and rage, received from the swords of his enemy wounds open as a grave; but he felt them not, and when, by the streams of blood, he found himself marked for pain, he refused to consider then what he was to feel to-morrow; but when his rage had cooled into the temper of a man,

and clammy moisture had checked the fiery emission of spirits. he wonders at his own boldness, and blames his fate, and needs a mighty patience to bear his great calamity." Shakespeare carefully discriminates between the wounds which pierce the heart and are at once fatal, and those which allow a few minutes, or even moments, of life. A stab which causes instant death wrings from the dying person one sharp cry of momentary agony, or sometimes purely spasmodic and mechanical, and then all is silent; and with the cry there is a sharp, convulsive movement of the limbs. So, Polonius utters one loud "Oh! I am slain!" Aaron imitates the squeal of the dying nurse, "Weke, weke!" Prince Edward, in "Richard III.," "sprawls," after his first stab. Those who do not die at once, but bleed to death, or are choked in blood, speak a little, know they are dying, but are not in pain, and have no convulsive movements.—*The Spectator*.

THE PROPER WAY TO GIVE ACONITE.—Dr. William Murrell makes some judicious observations on the correct plan for administering aconite so as to secure its most advantageous action. He observes that aconite acts best in small doses frequently repeated. Many practitioners get no good from aconite because they do not know how to use it. The dose of the tincture recommended in the British Pharmacopœia—from five to fifteen minims—is absurdly large, and no one with any regard for his patient's safety or his own reputation would ever think of giving it. The best way is to put half a drachm of the tincture in a four-ounce bottle of water, and to tell the patient to take a teaspoonful of this every ten minutes for the first hour, and after this hourly for some hours. Even smaller doses may be given in the case of children. The great indication for the use of aconite is elevation of temperature; the clinical thermometer and aconite bottle should go hand in hand.

CRYING OF THE FŒTUS IN UTERO.—Dr. A. Harlow, a well-known and highly esteemed physician of Detroit, Mich., reports a case (*Michigan Medical News*) in which he positively avers that the child while yet unborn uttered several distinct cries—at the time the membranes were ruptured and the child's head was in the superior strait. It was subsequently safely delivered by the forceps.

SMALL-POX IN HAYTI AND THE PROTECTIVE POWER OF VACCINATION.—A private letter from Dr. J. B. Terres, of Port-au-Prince, Hayti, gives some interesting facts regarding the prevalence of small-pox in that island. Dr. Terres says that the first case of small-pox was brought to the city of Cape Hayti from Port Plate, a city in the Spanish province, in the latter part of October, 1881, and from that point it spread rapidly over the entire island, not a city or even a plantation escaping the dreadful visitation. The first case appeared in Port-au-Prince on November 15, 1881, and the disease soon spread throughout the entire city. The largest proportion of the cases was of the confluent form, and the mortality was very great. From the best information Dr. Terres is able to obtain he estimates that the number of deaths on the island from small-pox has reached fully fifty thousand, and the disease is still doing its deadly work. No active means were taken to check its spread until about January 23, 1882, and even when the necessary measures were adopted by the Medical Jury there formed, it was found impossible to carry them out satisfactorily. The great trouble experienced was to make the masses understand that the spread of the disease was chiefly owing to the free intercourse of well persons with their sick friends.

Regarding the effect of vaccination Dr. Terres says: In Hayti vaccination has proved to be an almost absolute protection from the disease. A few exceptions have been noted, but these he attributes to the fact that the vaccine did not take properly. There were but few phy-

sicians at the time who could obtain vaccine matter, the supply furnished to those few was limited, and as the greater part of the matter was worthless the natural consequence was that with a majority of the people vaccinated it did not take. Dr. Terres used the bovine virus in tubes, quills, and on ivory points. He was most successful with the tubes, owing to the fact that the virus was better protected from the air, and was therefore less susceptible to atmospheric changes. The other forms, not being so well protected, lost their virtue soon after being imported to this warm climate. "I can say," he writes, "that I did not find one death occurring in cases that had been properly vaccinated, and from all the information that I have been able to gather from other physicians they uphold my statements."

OPHTHALMOLOGICAL STATISTICS IN THE UNITED STATES.—The following interesting statistics are given by Dr. W. S. Little in a recent article: The statistics of ophthalmic hospitals and ophthalmic work in general hospitals in the leading cities of the United States afford the following: Of 107,383 eye cases, 19,037 required surgical procedures, of which 862 were enucleation of the eye for some of the many forms of objective traumatism; principally on account of the dread of, or presence of, sympathetic irritation or sympathetic ophthalmia of the other eye; some for intraocular conditions, and a few for cosmetic purposes.

Thus 17.7 per cent. of ophthalmic work is operative, and 4.5 per cent. is enucleation of the eyeball. This percentage for the operation of removal of the eyeball should be higher than the statistics derived from the public clinics indicate, as this class of cases is more apt to seek private advice.

The importation of artificial eyes is about ten thousand annually, and recently the manufacturing of them has become a home industry.—*Philadelphia Reporter*.

CEREBRAL HEMORRHAGE AND FRACTURE.—An interesting medico-legal case was brought to the Pennsylvania Hospital recently. A man of intemperate habits was found drunk on the streets, and soon became comatose. He was brought to the hospital with symptoms of compression of the brain without evident hemiplegia, but with irregular pupils (right strongly contracted), and stertorous respiration, followed by death. There was no discernible wound of the scalp. A hemorrhagic effusion under the membranes, coinciding with a fracture of the right parietal bone, was found in the interior of the left hemisphere, and also a recent clot. It was believed that the small clot first caused apoplexy, and in falling the fracture of the skull was produced. It is further interesting as showing the relation between alcoholic poisoning and cerebral hemorrhage.

ESERINE AND BELLADONNA IN TETANUS.—Dr. Layton reports in the *New Orleans Medical Journal* a case of tetanus cured with the following prescription: Sulphate of eserine, one-half grain; pure glycerine, two fluidrachms; syrup of orange flowers, fourteen fluidrachms; water, two ounces. M. S. Teaspoonful, which contained one sixty-fourth grain or one milligramme of eserine, every hour. The glycerine was added to prevent the decomposition of the eserine, because this drug is affected even by exposure to the atmosphere. From January 10th, in the evening, the doses of eserine were given at intervals of an hour and a half; later, the time was increased to two hours, the remedy was continued until January 17th, when the child had taken, in all, three grains of eserine; the prescription was then discontinued, the only remaining trace of the attack being some rigidity of the jaws, which had entirely disappeared by January 30th.

Dr. Whiteley reports two cases of tetanus in the *British Medical Journal*, which he claims to have cured by belladonna in large doses. From twenty to thirty minims of the tincture were given every two hours.

Original Lectures.

ON RESPIRATORY MEDICAMENTS.¹

By PROFESSOR GERMAIN SEE,

MEMBER OF THE FACULTY OF MEDICINE, MEMBER OF THE ACADEMY OF MEDICINE, ETC., PARIS, FRANCE.

PART I.

GENTLEMEN: Among the cardiac medicaments there are few that may not modify the respiratory function in diseases of the heart. Digitalis, convallaria maialis, chloral, bromide of potassium, have this power in a marked degree, but their influence is indirect, being exercised through the medium of the circulation, or rather by their action on the heart, whose energy the most of them, and especially digitalis and convallaria, augment, causing the disappearance of general stasis, as well as passive congestions of the lungs.

By the side of these cardiac respiratory medicaments (or rather at their head) certain medicaments properly called *respiratory* deserve to be placed, and to which I directed attention three years ago when discoursing of the treatment of asthma by iodine. Thus far they have never been grouped or studied from the point of view of their common property, which consists in facilitating the respiratory function.

Foremost in this list ought to be mentioned:

I. Iodine, and its derivatives, iodide of potassium, and iodide of ethyl.

II. Arsenic, to which has been attributed from all time a favorable effect on the respiration.

III. Injections of morphine, which I have employed for ten years, and which were introduced into therapeutics by Huchard.²

IV. Erythrophleum, of which the physiological study, made with M. Rochefontaine, was published in 1880, in the "Mémoires de l'Institut." The active principle, erythrophleine, extracted three years before from this plant by Gallois and Hardy, has been made the object of new researches in my laboratory. The plant and its alkaloid have been for two years the subject of clinical studies which have not yet received publicity, but which show clearly the action of this medicament on respiration, as moreover in animals it possesses a manifest action on the circulation.

V. Pneumotherapeutics, by the aid of portable apparatuses.

VI. Quebracho. This is the bark of a member of the Apocynaceæ family, which grows in South America. Penzold has employed it in the form of an alcoholic extract (10 grammes of the bark, 100 grammes of alcohol); this extract is diluted with twenty parts water and given in teaspoonful doses. In emphysema he has had marked success; in other dyspnoeas the effect is less pronounced. Furthermore, the active principle is not yet known; aspidospermine (obtained from the bark) being a product not well defined. Having been unable to procure the plant in order to verify the somewhat contradictory assertions of divers experimenters, I cannot speak from experience of the effects of this respiratory medicament.³

I.—PREPARATIONS OF IODINE.

1. IODIDE OF POTASSIUM.—Iodide of potassium acts in an evident manner on the respiratory mucous membrane, and on the nervous mechanism of respiration. It is the remedy *par excellence* for asthma, and it constitutes the most useful medicament to combat dyspnoea of cardiac origin. If the lesion be a valvular one, its effects are less marked than if the lesion be one of the cardiac tissue itself; nevertheless, in both cases it generally suffices to banish, at least for a time, the element of dyspnoea. But before pronouncing on the existence of an asthma or of a cardiac dyspnoea, it is important to take into account a fact which I have often observed, and which has aforesaid led me into error. In a great number of asthmatics you observe at the apex of the heart, more rarely at the base, a very soft but distinct systolic murmur, which may cause you to apprehend a lesion of the valves; now this murmur, which seems to be located in the valves of the right heart, disappears altogether, and in a few days' time, by the sole fact of the disappearance of the asthma under the iodine treatment.

The other mistake, which consists in taking a case of simple cardiac dyspnoea for one of true asthma, is frequently made, as I had occasion to remark at the beginning of this course, when treating of the diagnosis of the pulmonary forms of heart disease.¹ This confusion, so prejudicial from the double point of view of diagnosis and prognosis, has not, practically, grave consequences, as far as therapeutics are concerned, for the same agent renders good service in both cases.

Formulae and doses.—One gramme and a quarter [about nineteen grains] per day; the dose to be gradually increased to two or three grammes. Prescribe the iodide in aqueous solution (1-20) or with syrup of bitter orange (10 parts of the salt to 200 of syrup or water); dose two to four teaspoonfuls every day, each teaspoonful to be diluted in a glass of water.²

If, by reason of the bad taste of the salt, some patients prefer to take it in wafers or capsules, they ought immediately afterward to drink freely of some diluent to prevent the irritant effect of the salt on the gastric mucous membrane.

Iodism.—The following are some of the inconveniences attending the prolonged use of the iodide: 1. A sanguinolent oozing from the buccal, and even from the bronchial mucous membrane, never amounting to an hæmoptysis, unless it be in the case of a tuberculous patient (beware how you prescribe iodine preparations to such patients). 2. Loss of flesh. This, instead of being a disadvantage, is often an advantage, especially when your patient is too stout; the excess of adipose being made to disappear, one obstacle to the free circulation of blood in the peripheral regions is removed. Other inconveniences are: 3. Loss of strength, which contraindicates a further use of the remedy. 4. Loss of appe-

cal Society of New York, in June, 1881, gave a favorable report on Quebracho. It was tried in thirty-two cases, embracing spasmodic asthma, with or without emphysema, cardiac dyspnoea, the dyspnoea of Bright's disease, aneurism, pneumonia, etc., and of these relief to a greater or less extent was afforded in twenty-one, no relief in ten, and in one the dyspnoea was increased. The respiratory centre was believed to be the seat of its action. *Ibid* New York Medical Journal, September, 1881 (Dr. A. H. Smith's report). Also THE MEDICAL RECORD, vol. XX., pp. 304 and 559.—TRANS.]

¹ *Ibid* my work on cardiac diseases (Diagnostic et traitement des Maladies du Cœur), p. 24 et seq. O. Doisy, Paris, 1883.

² [This formula may be expressed in terms of the old system as follows:

R. Potassii iodidi ʒ ijss.

Syrup auranti corticis ʒ iij.

M. Signa.—A teaspoonful three times a day in a glass of water. Dose to be gradually increased to two and even three teaspoonfuls.—TRANS.]

¹ Delivered in the Hôpital La Charité, and translated, with permission of the Professor, from advance sheets, by E. P. Hurd, M.D., Newburyport, Mass.

² Journal de Thérapeutique, 1877.

³ [This new remedy is now largely prescribed in the United States for dyspnoea of all kinds. It is given in teaspoonful doses of the tincture of the bark; is very disagreeable to the taste, and almost always produces nausea. The Therapeuti-

tite, which indicates a provisional suspension of the treatment. 5. Eruptions of various kinds.

2. **TINCTURE OF IODINE.**—It is without doubt the iodine which is remedial when we give iodide of potassium. To assure myself of this I have often prescribed (and with benefit) iodine alone, according to the following formula :

R. Tincture of iodine..... 5 grm. (gr. lxxv.)
Syrup of horseradish..... 150 grm. ($\frac{3}{4}$ v.)
Syrup of poppies..... 150 grm. ($\frac{3}{4}$ v.)

M. Signa.—Three teaspoonfuls a day; dose to be doubled as required.

The syrup of horseradish masks the taste of the iodine.¹

3. **IODIDE OF ETHYL.**—This compound, discovered in 1825 by Gay Lussac, is a mixture of two parts by volume of alcohol and one of hydriodic acid. This ether, which is without acid reaction, has an odor of chloroform, a piquant savor; it is volatile, boils at 64° centigrade, without being inflammable; exposed to the air, it turns a light brown color, from the setting free of a little iodine. Its chemical formula is C_2H_5I . For twenty years it was forgotten, till Huette experimented with it on himself and on one of his friends, with the object of replacing iodine in the treatment of phthisis, a disease which rarely calls for the employ of the iodine preparations. Since 1850, however, nothing more was heard of this substance till I conceived the idea of applying it to the treatment of dyspnoea from asthma or from other causes.

Physiological effects of iodide of ethyl.—In healthy individuals, and patients affected with dyspnoea, who have been made to breathe six to ten drops of iodide of ethyl six or eight times a day, the following results have been observed: After a few seconds the individual breathes with greater facility, and continues to do so for several hours. This effect, more marked when the person is laboring under dyspnoea, is quite perceptible in a perfectly healthy person. There is no anaesthetic or soporific action. The heart and circulation undergo no modification, and yet absorption of the medicament takes place immediately, for at the end of ten minutes iodine may be found in the urine. Sometimes an attack of coughing comes on at the commencement of the inhalation.

Modus operandi.—Iodide of ethyl, as well as iodide of potassium, has an incontestable action on the bronchial secretion, which it augments, at the same time that it increases its fluidity, thus facilitating the entrance of air into the pulmonary alveoli. Under its influence the respiratory murmur (before absent) returns, the tympanic resonance of emphysema disappears, the dry feeble râles of bronchial asthma give place to mucous râles.

This is the first effect of the iodide; its next action is on the respiratory centre by the medium of the circulation, which is now rendered more active. The respiratory centre, in the presence of an increased supply of blood, is re-enforced in function, and this explains the greater ease of respiration. In the third place, the ether in combination with the iodine, by its stimulus, enhances respiration, which becomes deeper and more energetic. These, then, are the indisputable advantages which this remedy possesses, not only in attacks of asthma, but in cardiac dyspnoea as well, and I have thought it deserving a very foremost rank among the medicaments of this group.²

¹ [A very good preparation containing iodine, much employed in this country, and especially commended for its palatableness, is the syrup of hydriodic acid. It is not mentioned in our text-books on therapeutics and materia medica, but it is sold all through the United States, and is in much repute as a remedy for asthma and for chronic bronchitis. The preparation which is most frequently prescribed in this region is Gardner's Syrup (manufactured at 170 William Street, New York), which is certainly an elegant preparation, and has been given both in spasmodic and in bronchial asthma with very satisfactory results. The syrup contains 40 minims of the dilute acid to the ounce, representing 6.66 grains of iodine. Two teaspoonfuls is an average dose. Many of our apothecaries make a syrup of hydriodic acid, which keeps well and can hardly be distinguished from Gardner's. Children take this syrup readily. It never irritates the stomach. See Wyllie's article on Hydriodic Acid a Substitute for Iodide of Potassium, in this journal, vol. xv., p. 454.—FRANS.]

² [Dr William Squire, of London, uses bromide of ethyl in similar cases. He drops on a square piece of lint twenty to thirty drops, which he requires to be inhaled. In renal dyspnoea, laryngeal spasm, some kinds of vertigo, and all diseases where there is vaso motor spasm, he finds it useful.—TRANS.]

II.—ARSENIC.

Arsenic has a very certain action on the respiratory muscles and on the bronchi, but it is slower in producing its effects than is iodine. Its effects on the heart, are, moreover, uncertain; it is not known just how the circulation is affected by it, or how it influences the oxidations of the economy. In general terms it is a medicament which spares the forces in staying the processes of denutrition, as is proved by the diminution in the production of urea and carbonic acid which attends its use. This property, however, does not attend the administration of the medicament in large doses, and ceases to manifest itself when the arsenical treatment is long continued. Gæthgens has, in fact, sometimes found an augmentation of urea eliminated in the urine; this is in accordance with what I have taught these twelve years. It cannot be depended upon, then, for any certain and constant effect in retarding oxidation, and thus lessening denutrition in the economy.

Lucien Papillaud has advised, as regular and systematic treatment of the cardiopathies, arsenic in combination with antimony, prescribing for each day two pills, each containing one milligramme of arsenious acid. It seems probable that the antimony affects more directly the central organ of the circulation than the arsenic, but the curative results of this treatment have never been proved, nor has it been shown to have been beneficial against the dyspnoea.

III.—HYPODERMIC INJECTIONS OF MORPHIA.

Morphia, used subcutaneously, is a powerful respiratory stimulant, but its action in facilitating respiration is not lasting, and grave inconveniences follow its persistent use: 1. It is sure to impair the appetite, digestion, and nutrition. 2. That morbid habit of the system, rightly called morphinism, with all its evils, will certainly be engendered. 3. The urinary secretion will be lessened; this is a great disadvantage in heart-maladies. 4. That dangerous form of respiration called Cheyne-Stokes respiration has been known (according to Filehne) to manifest itself in certain cases. Subcutaneous injections of morphia, then should only be resorted to during and for a paroxysm of dyspnoea.¹

IV.—ERYTHROPHLEUM AND ERYTHROPHLEINE.

Physiological experimentation.—Erythrophleine, discovered by Gallois and Hardy in 1876, is the active principle of the bark of *Erythrophleum guineense*, of the family of Leguminosæ. It is an alkaloid which has been experimentally shown to possess considerable toxic power and a remarkable action on the heart.

This action on the heart, as determined by experiments on animals, suggested to me the idea of introducing erythrophleine into the therapeutics of cardiac affections, but it was necessary as a preliminary undertaking to test by new experiments the toxic power of this alkaloid, and especially to study its principal physiological effects, notably those which are capable of registration by means of the hæmodynamometer, the sphygmograph, and the pneumograph.

This is the result of this investigation (I reproduce the summary report lately made by me to the Academy):

"Researches, commenced with frogs, have been continued with hares and dogs.² We mention only experi-

¹ [Some of the most formidable attacks of cardiac dyspnoea which have ever occurred in my practice have been associated with aortic insufficiency, with dilated left heart, and frequently with dilated atheromatous aorta. In these cases hypodermic morphia is the remedy *par excellence*—generally every other measure is impotent. I have been in the habit of using for an adult a saturated solution of sulphate of morphia in cherry-laurel water, commencing with five drops and increasing to twenty or even thirty. The larger dose is frequently required. Magendie's solution (sixteen grains to the ounce), is a very convenient preparation, of this, ten drops is an ordinary dose for hypodermic use. I have sometimes added, and with benefit, one one-hundredth grain of atropine to the injection, not believing in the therapeutical antagonism of the two drugs. Morphia subcutaneously is the most efficacious remedy against the cerebral anæmia as well as the dyspnoea of Corrigan's disease. I have, however, observed all the evils which Professor Sée above describes follow this treatment, to which I was compelled to resort to mitigate the violence of the attacks.—FRANS.]

² [These experiments were made with M. Rochefontaine.—FRANS.]

ments performed on the latter animals by the aid of hypodermic injections of a determinate solution of erythrophleine, since the limits of this article do not permit us to report experiments made on other animals by the same method or by other means of introducing the toxic agent into the organism. One centigramme of erythrophleine introduced under the skin of a dog weighing nine kilogrammes had no appreciable effect. Two centigrammes killed in two hours another dog weighing fourteen kilogrammes. In other words, in the dog the hypodermic injection of a solution of erythrophleine the strength of one milligramme per kilogramme of the animal did not produce evident toxic effects; one milligramme and a half, however, was fatal in two hours. Many experiments on different animals have proved that the toxic power of erythrophleine is about the same as that of the amorphous digitaline of Homolle and Quevenne.

"The first signs of intoxication consist in a slight degree of agitation and restlessness, followed by a period of prostration, which is succeeded by efforts of vomiting. The latter constitute the real initial symptoms of the poisoning. If the dose of the toxic agent be not too large, the vomiting ceases, and the animal rapidly recovers his normal condition. The circulatory apparatus is disturbed in its function as well as the digestive apparatus. We observe augmentation of the intra-arterial blood-pressure, irregularity, then slowing of the pulse, results which we find already recorded in the memoir of Gallois and Hardy. The period of retardation of the pulse is remarkable by reason of the regularity of the heart's action, the energy of each pulsation, and the uniformity of the intra-arterial blood-pressure. This pressure, in fact, is not modified by the respiratory movements, as it is ordinarily in the normal state, for the tracings of the hæmadynamometer and sphygmograph show that the undulations which, in an animal not subjected to the action of the poison, result from the influence of respiration on the blood-pressure, are not observed in the animal to which the erythrophleine has been administered. This period is followed by another, during which the pulse is extremely weak and rapid; the oscillations of the pressure under the influence of respiration reappear; this pressure diminishes gradually; the beatings of the heart, becoming more and more feeble, cease by moments, then are arrested definitely, and the blood-pressure becomes nil.

"The respiratory movements seem influenced directly by erythrophleine, although they are influenced *secondarily* by cardiac affections. In a general way they are at first somewhat retarded and of greater amplitude. When the cardiac pulsations are accelerated in the terminal period of the intoxication, the respiratory movements are extremely energetic and more frequent. In almost all the experiments, if not in all, the respiratory movements ceased at the moment of arrest of the heart. Several times at this moment the animal gave a loud cry. One, two, and even three minutes after the heart ceased to beat the respiratory movements reappeared, still energetic, lasting two or three minutes, then were arrested permanently.

"The functions of different parts of the nervous system seem disturbed by erythrophleine. Thus the faradic excitation of the thoracic ends of the pneumogastric nerves in the cervical region did not determine arrest of the heart in an animal poisoned by erythrophleine as it does in a well animal. The sudden fall of blood-pressure which accompanies the faradization is, however, manifested equally in both cases. The inhibitory or moderating action of the pneumogastric nerve on the heart is then modified by erythrophleine, and one can with this substance dissociate, as it were, physiologically the two circulatory phenomena which result from excitation of the cardiac filaments of the vago-sympathetics.

"The faradic excitation of the cephalic ends of the pneumogastrics, in an advanced stage of the intoxication, does not provoke that acceleration of pulse which it de-

termines (from the very first) in the animal that is in sound condition, but it acts on the arterial tension as it acts ordinarily, that is to say, by augmenting it; here we see a disjunction of physiological effects, under the influence of the poison.

"Faradization of the cardiac ends or of the cephalic ends of the vago-sympathetic nerves induces, then, in an animal in the normal state, the same modifications of pressure which it induces in an animal that has been poisoned by erythrophleine. The rhythm of the heart, on the contrary, is *respected* by these faradic excitations in the animal intoxicated by this alkaloid.

"In an animal killed by erythrophleine, the necropsy shows the heart in diastole, flaccid, and yet full of blood. Sometimes the ventricles are animated by a tremulous movement like that which succeeds to faradization of these ventricles. Generally the heart has not lost its electric contractility. The pneumogastric nerve has retained its action on the stomach. The excitomotricity of the phrenic nerves is ordinarily diminished, or even sometimes abolished, while that of the sciatic or of the cervical sympathetic is not lessened.

"To sum up, physiology demonstrates that erythrophleine acts not only on the heart but also on the respiratory apparatus, and this double action on functions so important incites us to make application of it to clinical medicine, and more particularly to the treatment of cardiac and respiratory affections."

Clinical applications.—All the facts which I have collected for the past three years enable me to affirm augmentation of the respiratory function in dyspnoic patients under the influence of one gramme (or thereabouts) of the alcoholic tincture of erythrophleine—I give this preparation in preference to the alkaloid, which is harder to obtain and to manage. In simple or cardiac asthma the movements become slower and of greater amplitude. The effects on the heart are less marked than in the case of animals; the arrhythmia does not disappear as it does under the influence of digitalis and convallaria; the pulse is not slowed; the valvular murmurs do not undergo modification; the diuresis is wanting. As a cardiac remedy, then, it presents no advantage; as a respiratory medicament it may to a certain extent supply the place of iodine and the iodine preparations.

A MEDICAL CONFIDENCE MAN IN NEW YORK.—The House Physician of Roosevelt Hospital, Dr. Van Vredenburg, writes: "A young man of about twenty-five years, low-sized, thick-necked, and rather common-looking, with a very confidential manner of speaking, has visited this hospital twice in the last few months, and is, I learn, canvassing the different physicians' offices of this part of the city. He described himself at his first visit here as surgeon to one of the Inman Line steamers, and at the second visit as assistant-purser to the City of Chester, Inman Line. He always purports being sent by some prominent physician, or else by a personal friend of the person to whom he applies. The first time he came here he offered to purchase surgical instruments and bring them in free of duty, claiming that as surgeon to the ship he could do so readily. The second time he had some "very good brandy" to sell, some that he claimed to have bought abroad, and more than sufficed for his own use. He desired the money with which to make his purchases advanced to him, but on neither occasion did he receive any commission. I wrote to Mr. J. G. Dale, agent of the Inman Line, and in his answer he disclaimed any knowledge of the man other than that he had heard of him and his doings. Said that there was no man by the name of 'Morton' (the name he gave here) attached to any ship of the line in any such capacity—I believe he said in any capacity."

A LARGE COLLECTION.—Professor Virchow has in his museum, at Berlin, a collection of six thousand skulls. It will be difficult for any one to get ahead of him.

REPORT OF A CASE IN WHICH A MYXOLIPOMA WEIGHING EIGHTY POUNDS WAS REMOVED FROM THE ABDOMINAL WALL.

By N. P. DANDRIDGE, M.D.,

CINCINNATI, O.

EARLY in September, Sarah H—, colored, was brought to Cincinnati and placed under my care by Dr. H. T. Bell, of Bethel, Kentucky. She was suffering from a tumor hanging from the left side of the abdomen, which had reached such an enormous size that it was necessary to suspend it in a strong sack, which was secured around her waist when she assumed the erect position. Most of her time was spent in bed, the tumor lying beside her. By my advice she entered the Cincinnati Hospital, and the following history is taken from the record of the case made by Mr. Lewis and Mr. Christopher, resident physicians, who at different times had charge of her:

S. H—, colored, aged forty. Moderately well nourished and developed, married, and mother of nine children, one of whom died when one week old, one at two weeks, and one at six months. When the tumor was not larger than an egg she aborted at one month. Eight years ago she states that she first noticed a small elastic tumor, the size of a goose-egg, in her side. It was located, according to her statement, to the left of the median line, and midway between the umbilicus and symphysis. It was freely movable beneath the integument, and was quite painless. At the end of two months the tumor was fully nine inches in diameter, and at this time she noticed a swelling to the left of the symphysis, which soon attained the size of a hen's egg, and remained that size until about two months ago. The exact relation of this second growth to the first she cannot clearly give. During all this time she has been able to make it disappear by pressure, when it appeared to enter the larger growth. During the menstrual period it would at times seem to increase in size. For the last two months it has been rapidly increasing in size, and now she is no longer able to reduce it. At present it measures 11 inches in circumference, and 7 inches from its apex to the spine of the pubis, and forms a mass, which presents to the left of the vulva.

During the last two years the larger tumor has also rapidly increased. Before that time she was able to do general field and house work, and the tumor, according to the statement of her physician, was about the size of a "ten or fifteen pound water-melon." About this time an incision was made into it, for the purpose of exploration, with however, only negative results, the incision healed readily. Menstruation has always been normal, and her bowels quite regular. She has never suffered any pain, and her general health has been good. She lies most of the time in bed, and only occasionally attempts to get up, and then always has to suspend the tumor in a large sack, which is fastened around her waist. In the recumbent position, the tumor lies beside her on the bed, and by its weight has drawn the umbilicus and linea alba considerably to the left. The line of attachment extends from above the anterior superior spine of the ilium to the symphysis, and the tumor as it lies on the bed seems a semi-fluctuating mass, which readily changes its shape on being moved. The integument over it is freely movable, and the growth appears to be encapsulated and lobulated.

September 22d.—Dr. J. C. Mackenzie, at my request, dictated the following as the result of his examination: "Liver dulness normal, and liver appears to occupy its normal position. Splenic dulness normal in extent and position. The umbilicus is drawn to the left of the median line 2½ inches. Above the umbilicus the linea alba is found in the median line, below it curves to the

left. The point of greatest divergence is about four inches below the umbilicus, where it is 4 inches from the median line; opposite the symphysis it is displaced 3½ inches. The line limiting the area of abdominal tympanites corresponds with the arc of a circle whose centre is 6½ inches below the ensiform cartilage, and whose radius is 6 inches. The line limiting the tympanites intersects the true linea alba 5 inches below, and a little to the left of the umbilicus. The above measurements were taken with the woman lying on her back, but slightly inclined to the left side, her shoulders supported, and the tumor on the bed beside her."

The following measurements were taken at this time: Long axis of tumor (nearly parallel with the axis of the body), 35 inches; circumference around the long axis, 56 inches; greatest circumference, 67½ inches; circumference of pedicle, 32 inches; short axis from line of tympanites, 16 inches. To the inner side of the large mass is a smaller one, apparently occupying the labia majora of left side, pear-shaped, 6½ inches in length, 4 inches in breadth, and 12½ inches in circumference at its broadest part. The consistency of the main tumor is different in different parts. In places there seems quite a distinct sense of fluctuation. The aspirator needle, however, introduced brought away only a small amount of clear lymph-like fluid, a similar clear fluid escaped drop by drop from some punctures made by a hypodermic needle.

The surface of the tumor is uneven, indicating a division into lobules. Between two of these, in a slight depression across the growth, a cord-like body can be traced from a point two inches below, and to the right of the umbilicus, for a distance of fourteen inches, until it is lost in the thickened integument. Sixteen inches from the umbilicus is a shallow circular ulcer about one and a half inch in diameter, which is covered with a dry scab. This ulcer is said to have existed unchanged for two years. The integument over the tumor presents different degrees of thickening in different parts. Near to the abdomen, on the anterior surface, it presents a natural appearance. Toward the periphery of the mass it becomes thickened and indurated, and its surface presents small depressions. Even in its thickest portions the integument can be made to move readily upon the underlying growth, showing that the tumor is surrounded by a loose connective-tissue capsule. Within the line limiting the area of tympanites coughing gives an impulse to the hand on the abdominal wall from the underlying intestines. This cannot be felt outside this line. From the under surface of the tumor there escapes at times a lymph-like fluid.

The tumor was seen by my colleagues of the hospital staff and a large number of other physicians, and the diagnosis of a subcutaneous fatty tumor generally concurred in, although a subperitoneal origin was regarded as more probable by some. Various views were expressed as to the exact relation with the abdominal cavity, and whether or no some of the abdominal organs might not be found in the mass. Diametrically opposite views were entertained in regard to the propriety of attempting its removal. After careful observation my own conclusion was that the abdominal wall had been simply dragged down by the weight of the tumor, and that the line of tympanites marked the limits of the abdominal cavity. This reached some distance over the front of the tumor.

The smaller tumor was supposed to be a hernial protrusion, though the possibility of its being simply a lobule of the general growth was kept in view. The woman was exceedingly importunate that an attempt should be made for its removal, and was not the less determined when the great dangers were explained to her. So with the consent of my surgical colleagues I determined upon operating.

The mass was so heavy and so unwieldy that it was difficult to determine how best to handle it during the operation. A number of experiments were made by

strapping it securely to a board, but all proved unsatisfactory, so finally it was decided to place it upon a small stand beside the operating table and allow the tumor to overhang each end; in this way it was found the pedicle could best be exposed without the necessity of moving the entire mass. It was decided to make an incision over the anterior surface, separate the tumor from the abdominal wall, and complete the operation by cutting through the integument covering the under surface from within outward. The especial dangers which were foreseen and had to be provided for were, in the first place, the possibility (or probability) of opening the abdominal cavity and the escape of intestines. In case this accident occurred large flat sponges were provided, by which the opening could be closed and the bowel prevented from escaping, or if that was not possible, at least protected until the removal of the tumor was completed. The danger to be feared was the extreme loss of blood. To provide for this, a large number of hæmostatic forceps

were to be provided, and all bleeding points at once secured, and, where it was possible, it was determined to ligate all large vessels before cutting them. Pressure by means of broad sponges was expected to control capillary hemorrhage; and finally, as an extra precaution, the rubber tourniquet of the Esmarch bandage was to be thrown loosely round the pedicle to be tightened if necessary.

In case of collapse from hemorrhage or shock, two of the assistants were at once to apply Esmarch bandages from the toes to the hips, while stimulants were to be given, if necessary, hypodermically and by the rectum, and if these means failed a battery was ready to be used, if needed.

October 8th.—The tumor was compressed by a number of Esmarch bandages, but no information of importance was gained by this.

October 12th was appointed for the operation. The day previous the patient developed a malarial attack, followed by some dysenteric symptoms and the appearance of the menstrual flow. This, of course, necessitated the postponement of the operation. The unfavorable symptoms soon subsided, and the 19th was determined on for the removal of the tumor. On the 18th there was a renewal

of the malarial attack, though in a milder form. Quinine was now freely given, and as the outbreak had occurred after an interval of exactly seven days, it was thought best to let that period pass over before deciding upon a date for the operation. October 25th she was quite well, so Monday, October 30th was fixed. These delays in no wise affected her spirits, or her determination to have the operation at least attempted. About this time she succeeded one day in reducing the smaller tumor. Examination showed that the mass had not been fully reduced, but the hand could enter what seemed to be a large hernial opening. This opinion was afterward shown to be an entire mistake.

October 29th.—Dr. Mackenzie examined her heart and found an indistinct systolic bruit at apex, transmitted to the left, and some occasional irregularity in the heart's action. The apex beat was heard outside of the nipple line. The general plan of operation was fully discussed with my colleague, Dr. Walker. The arrangements were

all entrusted to Mr. Christopher, who, as interne, had charge of the case, and proved to be most satisfactory, every emergency being readily met without involving any delay whatever in the operation. The tumor was removed October 30th, at 11 A.M., in the amphitheatre of the hospital in the presence of the medical class and a large number of the physicians of the city. A hypodermic of morphine one-fourth grain, and atropine one ninety-sixth grain, was given about fifteen minutes before the administration of ether was commenced. Dr. E. W. Walker and the entire resident staff acted as assistants.

As decided beforehand, the tumor was allowed to lie upon a small stand by the side of the operating table. A sheet, rolled up, was placed beneath the pedicle, so as to raise it somewhat from the body, and the rubber tourniquet of the Esmarch bandage was thrown loosely around it, to be tightened in case of necessity. The main body of the tumor was removed in fifteen minutes and the entire dressing completed in forty-two minutes.

The tumor weighed seventy-one pounds immediately after removal, and as a considerable quantity of mucoid substance escaped and was lost its actual weight must have been, at least, eighty pounds.

The incision was commenced on the anterior surface, well to the outside of the left anterior spine of the ilium, and carried at once down to the surface of the tumor.

It was extended for ten or twelve inches, and the portion of the tumor thus exposed was found to be surrounded by loose connective-tissue, which was readily broken down with the hand, and the separation of the growth from the abdominal wall easily effected. All bleeding points were at once secured. The incision was carried rapidly across the whole anterior surface, following a line about three inches outside of the line of tympanites, all bleeding being controlled as we proceeded. The separation of the tumor was now continued, and effected principally by the hand, though at times the knife was necessary. The separation was readily effected; before, however, we had proceeded very far I suddenly found a considerable mass of intestines at the bottom of the wound, which had escaped from a large hernial opening. Without waiting to reduce them Dr. Walker at once covered the mass with a large flat sponge, and so protected them during the remainder of the operation, which was proceeded with without delay. Indeed, so successful was he in this that only very few persons knew that this complication had arisen. The circulation now began to flag, and soon the pulse at the wrist entirely disappeared. Esmarch bandages were at once applied from the toes to the hips by assistants who were ready for this emergency, if it occurred, and two ounces of whiskey thrown into the rectum. While these measures were being carried out, the work of separating the mass continued without interruption. As we approached the smaller tumor great circumspection became necessary, until it could be definitely determined whether we should encounter a hernial sac or only an independent lobule of the general mass. Before proceeding to a minute examination on this point, the main growth was separated partly by cutting, but principally by tearing through the portion connecting it with the smaller growth, and then the separation was completed by rapidly cutting through the integument and tissues which remained on the under surface, and as the attachments were severed, two assistants grasped the mass with large butchers' meat-hooks, and swung it free from the body. Large sponges were at once crowded against the exposed surface, while the smaller tumor was explored and found to be only a lobule of the general growth and easily removed. The protruding intestines were now returned. They were found to have escaped from what was evidently an old hernial opening an inch and a half in diameter. This was securely sewed up by a continuous suture of catgut. The bleeding points were now rapidly secured, and the surface of the wound washed off with a weak solution of carbolic acid, and the edges of the integument accurately adjusted by sutures, after a large-sized drainage-tube had been secured in place, and the whole covered with a thick mass of absorbent cotton. Hot bottles were at once applied, and the patient was covered with blankets. The Esmarch bandages were allowed to remain in place, and the foot of the bed elevated, and a rectal injection of two ounces of whiskey given. The shock of the operation was very profound, and she rallied slowly.

By 1 P.M. she was fully conscious; pulse weak and 108. She complained so much of the pain given by the rubber bandages, which had been allowed to remain in place, that they were removed. 2 P.M.—Pulse, 92, weak and intermittent; temperature, 98. Complaints of some pain in the wound, for which a hypodermic of one-fourth grain of morphia was given.

During the afternoon she passed several ounces of blood from her bowels. No blood in urine, which was freely passed. This hemorrhage from the bowels was, I think, very possibly due to the rupture of some of the hemorrhoidal veins, caused by the increased blood pressure produced by the compression of the lower extremities by the rubber bandage.

October 31st, A.M.—Temperature, 98; pulse, 108. Slept well. Pulse stronger. Dressing unchanged. About noon she became restless, and was given morphia one-fourth grain, champagne and ammonia carbonate every

hour. 4 P.M.—The dressing was removed, and the wound covered with large, flat sponges, soaked in a saturated solution of boro-glyceride, and held in place by bandages. The wound was free from odor; there was no pus, and the edges were in close apposition. A warm one-half per cent. solution of carbolic acid was syringed through the drainage-tube, washing out some clots of blood. Temperature, 99.2; pulse, 108. This washing out was ordered repeated every two or three hours.

At 6 P.M. the tube was found impervious, and no fluid could be forced through; at 7 P.M. a long cylindrical clot was washed out, and at 11.30 the tube was found quite free. The circulation continued feeble, the pulse ranging at a little more than a hundred. There was at no time any elevation of temperature. The surface of the wound looked well. The edges were well apposed, though slight traction easily separated them, showing that repair was not going on. Only once was there any odor. Champagne and carbonate of ammonia, and milk, were alternated every hour. At times there was some tympanites. The slight pain which was complained of was easily controlled by morphia.

November 3d.—Has had a natural stool, and passed a considerable quantity of flatus.

On the morning of the 4th I found her abdomen greatly distended, her countenance pinched, and respiration rapid and shallow. An injection was ordered, which brought away a good deal of flatus, which was followed by some relief.

During the night she became restless, complained of pain in the abdomen, which could not be controlled by morphia. She died Sunday morning, six days after the operation.

The autopsy was made by Dr. Joseph Eichberg, pathologist of the hospital.

"Body that of a colored woman, somewhat emaciated, and above medium size. Rigor mortis marked. Autopsy twelve hours after death. In the external abdominal wall, on the left side, beginning above and behind the crest of the ilium, and extending downward almost to the symphysis, was an incised wound fourteen inches long, the edges of which had been united by sutures almost the entire length. From the ends of this cut extended the extremities of a large-sized drainage-tube. Hanging down over the pubes was a pouch covered with integument, $5\frac{1}{2}$ inches long, 3 inches in breadth. Taking out the stitches, the edges of the wound were found to be in a sloughing condition, and the wound itself filled with a broken-down, decomposing tissue. No union had at any point taken place. The pouch was filled with a very offensive fluid, composed of broken-down tissue. At one point the floor of the wound was constituted of peritoneum, the edges of which had been stitched together by a continuous suture. This point was found to correspond to the internal inguinal ring. On opening the abdominal cavity the intestines were found enormously distended with gas, and the diaphragm was pushed up to the third intercostal space. The intestines were glued together by recent lymph, present in a very slight amount. In the internal inguinal ring of the left side, which had not been completely closed by the suture, was found a hernial protrusion of the intestinal wall involving only the unattached border, and forming a protrusion like a glove finger; length, three-fourths of an inch.

"This part of the intestine was situated twelve inches above the ileocecal valve. There was no interruption in the intestinal canal at the seat of hernia. The mesentery did not project through the opening, and was not connected with the tumor. The edges of the opening in the peritoneum had not become adherent, as shown by removing the suture.

"Lungs were congested and slightly emphysematous.

"Heart was soft and flabby, and the right ventricle filled with a large and partially decolorized clot.

"Kidney congested and slightly fatty; liver, normal.

"Both large and small intestines contained yellowish fluid feces; mucous membrane normal; stomach distended with gas; spleen small and firm; brain not examined. Cause of death peritonitis and failure of heart."

The immediate cause of death was undoubtedly the interference with the action of the heart and lungs, due to the great distention of the small intestine. The hernial protrusion did not involve the whole calibre of the bowel, and did not offer a mechanical obstruction to the passage of the intestinal contents. It probably, however, produced a paralysis of the peristaltic action, and thus allowed the over-distention, which was probably the immediate cause of the peritonitis. From this examination it is apparent that there was no depurative action in the wound itself, even the surfaces of the peritoneum, when they were brought together at the hernial opening, did not adhere, but fell apart as soon as the suture was removed. After the operation the circulation was always feeble. Her moral condition throughout was excellent, and one morning she expressed herself as feeling "splendidly." She did not, however, possess vitality enough to repair the immense wound left by the operation. The magnitude of the operation will be appreciated from the fact that the cut edge of the integument, measured on the tumor after removal, was sixty-two inches.

Dr. Eichberg further reports: "The tumor presents, on microscopical examination, the appearance of a growth made up of several kinds of tissue, small lobules of adipose tissue are intersected and separated from each other by tracts of a pearly opaque color, and in the central part of many of these tracts a soft, gelatinous, transparent, semifluid substance is found. The skin is freely movable over the tumor, with which it is connected by loose cellular tissue. Immediately after removal a large quantity of this gelatinous fluid escaped. There is not any distinct investing capsule, though the outer portion of the growth is made up of a tolerably thick band of this pearly substance. The circumference of the skin flap is sixty-two and one-half inches, the largest diameter twenty-eight inches, the transverse nineteen, and the thickness of the growth is nine inches. Judged by the microscopical appearances only, the tumor appears to be a compound of myxoma and lipoma, an association not infrequently met with in subcutaneous growths examined under the microscope. The compound nature of the growth is very evident. A very large part of the growth is lipomatous structure. The mass of fat-tissue is intersected by bands made up of longitudinal fibres and spindle-shaped cells with long oval nuclei. In places these bands acquire a very considerable size, so that they fill almost the whole field of the microscope, and remind one strongly of a spindle-celled sarcoma. In other places, small groups of what appear as round cells may be seen—these groups are possibly only the above bands of tissue cut across. The greater part of the pearly opaque bands is made up of a very fine, wavy connective tissue, which in parts has evidently undergone mucoid softening, all trace of fibres here being lost, and the specimen presenting the characteristic stellate cells in a large mass of homogeneous intercellular substance. The vessels ramify in the bands of connective tissue, and their walls are thickened. From its macroscopic and microscopic appearances, then, we may classify the tumor as a myxolipoma, the mucoid change being evidently a secondary degeneration.

"The only doubtful point would be in reference to the nature of the bands of spindle cells, which are probably connective-tissue cells in process of fibrillation, the connective tissue being, like the other parts of the tumor, in a condition of active growth."

The tumor which has thus been described is the largest lipoma of which I have been able to find a record. Ashhurst speaks of one referred to by Gross, which weighed seventy pounds. The largest mentioned by Bocca weighed twenty-three kilogrammes (about forty-

six pounds). In the majority of cases where fatty tumors have reached such an enormous size, they have been situated upon the back. The question of operation in the above case involved peculiar responsibility. The opinions expressed by those who saw the case presented very diverse views on this point. While the nature of the tumor was generally agreed on, its relation to the abdominal cavity was a question upon which there was decided difference, and whether or not the mass contained intestines, or even some of the other abdominal organs. Whether the growth could be removed without fatally compromising the abdominal cavity, and whether the woman could support so violent a shock as the operation would necessarily involve, were points upon which I had to encounter a variety of expression. The decision to operate was only arrived at after six weeks of careful daily observation, and the result, I feel, fully justified the attempt.

The illustrations, taken from photographs, give a very exact idea of the size and attachment of the tumor.

EPIDEMIC OF IMPETIGO CONTAGIOSA.

By WOOSTER BEACH, M.D.,

ATTENDING PHYSICIAN, NORTHEASTERN DISPENSARY, NEW YORK.

ABOUT a month ago a child was brought to the dispensary with two or three peculiar spots on the calf of the leg that appeared to be the remains of rather superficial pustules. They appeared to result from ecthyma, and I entered them on the record as that disease, but with an interrogation mark after the name.

About two weeks afterward two more cases presented themselves, in which the appearances observed in the first case were seen, but besides there were numerous other lesions sufficiently well marked for me to be able to render a diagnosis of impetigo contagiosa with certainty.

Soon after this three more patients, attacked in the same way, coming to the dispensary, it struck me as probable that the origin of the trouble might be traced to a single source. Instituting inquiries I found that the last three patients had recently removed from Steinway's settlement, near Astoria, where, I was informed, there had been an outbreak of the disorder, affecting some forty or fifty persons.

Proceeding to this place with my friend Dr. Carter, we were somewhat disappointed to find our anticipated field of study narrowed down to about half a dozen cases. Some forty to fifty families had left the place within the preceding two months, in consequence of a labor strike, carrying with them a number of the objects of our search. However, a description of some of the examples that were left will probably prove as instructive as if a larger number had been reported, as the lesions mentioned in those examined would simply have to be repeated in a more extended number of observations.

CASE I.—Willie B——, aged three years, a healthy-looking, well-nourished child of German parentage, has had the disease a little over a month. His mother states that about a week before its first appearance he was seen to kiss a little companion whose face was broken out.

On Willie's chin are two patches, of rather irregular outline, but inclining to an oval shape, having their centres beneath each angle of the mouth and nearly meeting, so as almost to cover the front part of the chin. They have a moist appearance, and are partly covered with a soft, yellowish crust, broken irregularly, and streaked with blood; evidently changed by scratching. On the upper lip are three, and on the other parts of the face five pustules, varying in size and development, none of them very recent. Also on the face were eight dark red, non-elevated spots, with edges fading off into sound skin, evidently the vestiges of pustules. On the head were ten patches, distributed irregularly over the

scalp. They were all of nearly equal size, about half an inch in diameter, covered with a thick, dirty-yellowish crust, in which the hair was matted. Detaching these crusts, which were slightly adherent, a dry, faintly reddish base was exposed. On the extensor surface of the right forearm and wrist were five, and on same aspect of left corresponding parts were six, pustules of quite recent origin. They were from split-pea to finger-nail in size, roundish, flat, covered with crusts looking like soaked thick brown paper. Their circumference occasionally showed a line of redness. The crusts did not fully extend over the pustules in some instances, pus showing at its edges—so to say, it was not quite large enough to fit. There was no well-marked umbilication observed, except in one pustule on the left arm.

With this patient, as in all the other cases, there was a good deal of itching, especially on the chin, after the disease had existed some three or four weeks.

CASE II.—Henry B—, four years old, apparently in good health. Eruption confined to chin, beneath the right angle of the mouth, and presents same appearances as the similarly located lesion in Case I. Said to have been communicated by kissing.

CASE III.—Sarah S—, four years old. Reported to have caught the disease from Willie B—. It commenced two months ago on the cheek, once extended to the chin, beneath the angle of the mouth, the only location it occupies now. There are five other children in the family to which this patient belongs, one an infant. No means to prevent contagion has been taken. They frequently kiss each other, sleep together, and come in close contact in other ways, yet but the one member of the family is affected.

CASE IV.—Miss R—, ten years old. Had the disease for about three weeks; at present it has almost entirely disappeared. She is attending school.

CASE V.—William Y—, healthy-looking, very well nourished child, three years old. His mother states that four weeks ago a breaking-out appeared on the chin, then crept along as far as the ear, by a succession of sores, in about two weeks. Now, December 8th, the broken pustules have much the same appearance as those already described.

CASE VI.—Ann Y—, sister of the above. Apparently healthy. The first lesion made its appearance over the eyebrow, from which place it has extended by successive crops to the cheek. The disease has also appeared on her arm.

CASE VII.—Mrs. Y—, the mother of Cases V. and VI. The disease appeared about a month ago on the chin and has not extended. It resembles an eczematous patch that has been scratched and torn by the finger-nails, and this description will apply to most of the older patches in the cases related.

In Cases V., VI., and VII. an ointment of oxide of zinc was ordered to be applied freely to all the diseased surfaces. A week later the old lesions had nearly disappeared, but one new pustule on the leg of each of the children had made its appearance: about two weeks later quite a plentiful crop appeared on the forehead of pea-sized pustules, most of them umbilicated. New pustules also broke out on the body.

There seemed to be no evidence to support the claim that this disease depends on vaccination as a cause. Some of those affected had been vaccinated at various periods preceding the time that they were attacked, while others had not been vaccinated at all.

The site of this epidemic is a recently built-up district on the south shore of Long Island Sound. Malaria, as usual in so many suburban places, is the bane of the inhabitants. All the cases that I saw and could learn of were located on a single avenue of two blocks, directly exposed to the winds blowing from the water and over salt meadows and sunken lands.

Impetigo contagiosa is seldom confined to single cases in its attacks, two or more happening together; but it is

rather unusual for it to assume proportions that are extensive enough to be called epidemic.

Most writers on the skin represent the affection as self-limited; lasting about ten days. But one of my cases recovered in less than three weeks, and most of them have been afflicted more than two months. Further, the lesions are said not to give rise to itching, but this symptom has been prominent in most of the patients after the eruption is about two weeks old.

The disease has been described by so many able and distinguished dermatologists, since 1864, when Tilbury Fox first called attention to it in the *British Medical Journal*, that the present article may be regarded as a superfluity. To redeem it from a charge of this kind, I may say that some phases of the disease in the cases presented are either novel or are not noticed by writers. A further necessity of drawing attention to the disorder at this time is, that it is contagious. The families with their children still suffering from it are distributed through the city, and some of them will pretty certainly fall under the notice of physicians who, in all probability, will be quite unprepared to make a diagnosis. The breaking out of a "catching" disease with which the public are not acquainted occasions alarm and consternation, and a rush is made to the physician generally with greater anxiety to ascertain if it is dangerous than to ask for treatment.

To those moderately informed on skin diseases the diagnosis is not difficult. It may be mistaken for ecthyma, pustular eczema, impetigo (same name, but quite distinct disorder), varicella, and in its later stages possibly for herpes febrilis (fever cases). If the contagious element is discovered a mistake can scarcely happen.

In the following table I have endeavored to present the differential diagnosis, so that the lesions and symptoms of impetigo contagiosa may contrast directly with those resembling it of the diseases named:

<i>Impetigo contagiosa.</i>	<i>Pustular (impetiginous) eczema.</i>
Small, roundish, flat, discrete, variously sized pustules.	Minute pustules agglomerating, very itchy.
On head, isolated and few in number.	On head, usually numerous, inclined to coalesce and cover large surface.
	<i>Ecchyma.</i>
Favorite location on face, then on arms, superficial; slightly inflamed base; may occur in the robust.	Lower extremities usually attacked; somewhat deep; firm, sensitive, inflamed base; mostly affects the debilitated.
	<i>Impetigo.</i>
Pustules flat, inclined to spread at periphery, to unite when close together.	Pustules full and rounded; do not increase in size, nor rupture nor coalesce.
	<i>Varicella.</i>
	Usually small vesicles on face and body.

RECOVERY AFTER A LOW TEMPERATURE.—Dr. F. A. Hubbard, of Taunton, Mass., sends us the following interesting case: "An intoxicated man spent the night of December 18th in an open coal-shed. He had the protection only of ordinary clothing, and when found, late the next forenoon, was apparently dead. Closer inspection revealed signs of life, and after about six hours our efforts to restore him were successful. His temperature was taken about four hours after he was found. The thermometer was a verified, self-registering one, graduated from 90° upward. The register could, however, be shaken down for a space equal to 5° more. It was so fixed and placed in the rectum, where it remained for seven minutes. The register was not lifted at all. The patient's temperature, therefore, did not exceed 85°. We cannot say how much lower it was. Shortly after consciousness was regained the axillary temperature was 100.2°. The patient was attended by Dr. F. D. Tripp and myself. The means used were flagellation, external heat, hypodermic administration of digitalis, atropia, and strychnia, with aromatic ammonia by the mouth."

TISSUE METAMORPHOSIS AND SLEEP.

By GEORGE W. RACHEL, M.D.,

NEW YORK.

THE excellent article in a recent issue of THE MEDICAL RECORD by Dr. J. Leonard Corning, on "Sleep," I have read with great interest. Since I have given the subject some thought and attention, I may be permitted to say something about it.

In order to approach the matter from the right direction, it will be best to refer to "exhaustion" of the tissues in general. The word in use with German physiologists, *Ermüdung* (= fatigue), is probably more correct, because it implies only the *inability of the tissue to perform its function* (secretion, contraction, cerebration, etc.), but does not imply that the cause of this inability is exhaustion of material available for such functional activity. For example, we know that, in experimenting on muscles, such a state of "fatigue" is induced by prolonged artificial tetanus. A muscle thus treated will at last no longer respond to the application of the electrodes, and no contraction will ensue. If the muscle is still part of the living body, a short rest will cause a restitution of functional activity, and a contraction will be produced by a renewed application of the electrodes. Now, it might be surmised that this "fatigue" is due to actual exhaustion of the muscular tissue, and that the period of rest had served to cause a restitution of the wasted material. That such is not the case is shown by experimenting on a muscle which is cut out of the body. If such muscle is reduced to the state of "fatigue" by tetanizing, it may be regenerated, made contractile again by washing it out, either with blood or with a 0.7 per cent. solution of sodium chloride, which is rendered feebly alkaline by a little sodium carbonate or kreatinine. By slowly injecting this alkaline fluid, the products of tissue-waste are taken up and removed, and the acid condition of the "fatigued" muscle changed into one that is alkaline. Now the muscle will again respond to an electric discharge.

Professor Johannes Ranke, of Munich, has made, among others, these relations a special study, and has shown that the "fatiguing" substances are principally carbonic acid, lactic acid, potassium biphosphate, and other acids and acid salts, *i.e.*, the products of the tissue-metamorphosis which sustains the functional activity of the muscle. Ranke was enabled to show by direct experiment that the action of these substances is that which causes "fatigue." For this purpose he impregnated a fresh muscle with beef-broth, which contains them, and thereby reduced it instantly to an extreme state of "fatigue," exactly equal to that produced by prolonged functional activity.

It is not necessary to go into detail with regard to these processes; suffice it to remind the reader once more that it has thus been demonstrated that the "fatigue" produced in the muscle is not "exhaustion." From these experiments it follows, furthermore, that the material utilized during functional activity is not derived from the blood supplied to the muscle, but is present in its tissue. Otherwise it would be impossible for an isolated muscle to contract after the "fatiguing" substances have been removed by injecting the alkaline fluid. *The oxygen, as well as the oxidizing material, are contained in the substance of the muscle, independent of the blood-supply, and only after these give out (more especially the former, the oxygen) can there be actual "exhaustion."*

Fortunately, we have a series of valuable experiments bearing on this matter, recorded by Pettenkofer & Voit, which confirm Ranke's views in this respect. In these it was shown that the amount of oxygen inhaled has not a direct influence on the amount of carbonic acid exhaled during a given time. The subjoined figures will speak for themselves:

DAY OF REST.

	Oxygen inhaled.	Carbonic acid exhaled.
6 A.M. to 6 P.M.	234.6 grms.	532.9 grms.
6 P.M. to 6 A.M.	474.3 "	378.6 "

WORK-DAY.

6 A.M. to 6 P.M.	294.8 grms.	884.6 grms.
6 P.M. to 6 A.M.	659.7 "	399.6 "

Thus it is seen that the oxygen used in the course of the day has for the greater part been "stored up," as it were, during the preceding night. For this purpose it must become an integral part of the tissue, must be a component element of the chemical combinations constituting such tissue.¹ The importance of this fact will be perceived at once.

In the first place, the part played by the blood must materially differ from what it is usually conceived to be. Its importance as a purveyor of oxygen during activity is greatly reduced, while its purifying function, by which the "fatigue-producing" substances are removed, can hardly be over-estimated.

On the other hand, oxygenation by the blood during rest must appear in a very different light, since we know that it is greater at this period than during activity. For, while during the latter state all the oxygen of the blood is consumed, in addition to that present in the tissues, this is not the case during rest. Here all the oxygen supplied is not applied to tissue metamorphosis, a comparatively small part only being thus employed; the balance goes to the tissues and becomes an integral part of the various substances composing it, a most important process, which has hitherto, at least to my knowledge, not been duly recognized, more especially in its bearings on the subject of sleep.

This cannot be said of the other task performed by the blood; it has always been known that the purifying action of the latter partly consists in its absorbing the products of tissue waste. But we shall understand it more fully in the light of the experiments above alluded to. This action goes on incessantly during rest, as well as during activity; but it is essentially different in the two states. During functional activity of the organ, it is of great importance by preventing too great an accumulation of the waste products then constantly forming at a rapid pace, which would otherwise lead to such an increase of their "fatiguing" action as might entirely prohibit activity. During rest, on the other hand, it is evident that the waste products then carried away by the blood are of an entirely different character; they constitute all the fixed acids and acid salts which, although being oxidized, are still held by the tissues, and may be considered the surplus which cannot be eliminated by the blood during activity, its capacity in this respect being limited.

This surplus is of the utmost importance for our consideration, since it is the *direct cause of sleep*. For this slow accumulation of "fatigue-producing" material must take place in every organ of the body, especially in those which are incessantly active, until its amount is so great as to render further activity impossible. This may possibly occur at the time when the amount of disposable oxygen in the tissue is nearly exhausted, although we have as yet no means to know that. (Ranke² contends that: "Fatigue due to want of decomposable material has as yet not been observed; although many physiologists assume that such a state does exist, its existence is more than improbable.")

Of all the tissues of the human body, the brain is certainly an incessantly active one. While we are awake,

¹ That such is actually the case, is best illustrated by Valentin's observations on hibernating animals. He found that during hibernation marmots would at certain times show a slight gain in their weight, although they had been giving off small amounts of carbonic acid and water. Our readers will perhaps recall the experience of Dr. Tanner, who was also reported to have gained in weight slightly, a paradox easily explained by an accumulation of intra-molecular oxygen.

² Grundzüge der Physiologie des Menschen. Second edition, p. 107.

our brain is constantly occupied, either with receiving external impressions, or with calling up from our vast store of former impressions those that suggest themselves by the association of ideas. This incessant mental activity is the psychical equivalent of a multitude of chemical processes in the ganglionic cells and nerve fibres, which, to the number of many millions, constitute the cerebral tissue. The general tendency of these chemical processes is the same as in all other tissues, viz: oxidation. The waste products, therefore, are similar: Carbonic acid, potassium, biphosphate, and other acid salts are also formed here, only the *fixed acid* differing from that found in the muscles (lactic acid).¹ Thus the brain, as well as the muscles, shows an acid reaction after a long period of activity, while both when at rest have a slightly alkaline reaction. They differ, however, in this: The brain normally contains a greater proportion of water than blood, while with muscular tissue the reverse obtains; and further, the brain is drained of its water during activity, while the muscles are rendered richer in water by continued exercise. The important influence of this on endosmosis and exosmosis will be readily perceived.

After having thus roughly sketched the various conditions found in certain tissues before, during, and after tissue metamorphosis, we may now refer to the part which tissue metamorphosis plays in the production of sleep.

We have had occasion to point out one of its chief causes, if not the chief cause, viz.: The gradual accumulation of certain products of tissue waste, which, as a rule, are not wholly removed by the blood during activity. These we have found to be such as have the physiological property of inducing "fatigue," if a certain amount of them be present. This explanation has been anticipated by Durham, whom Dr. Hammond cites as saying: "A probable explanation of the reason why quiescence of the brain follows normally its activity, is suggested by the analogical fact that the products of chemical action interfere with the continuance of the action by which they are produced."

It, however, is not absolutely necessary that the substances which exert a "fatiguing" influence on the brain must have been produced in the brain itself. We have seen that the waste products are very similar all over the body, *i.e.*, results of oxidation. Therefore a person may have done very little real brain-work during the day, and yet he or she will be just as sleepy, or even more so, than another who has done a certain amount of literary or other mental labor only. The explanation of this apparent paradox is, that the "fatiguing" products accumulating in the muscular system are partially taken up by the blood and carried to all other organs. Now, the brain normally contains more water than the blood, and although this condition is somewhat modified through the daily brain-action even of a person occupied with muscular work, the result still will be a slow imbibition of this "fatiguing" substance. But the latter also acts on the heart and on the vascular system generally. The heart's action is thus retarded, not only by their direct action when they pass through it in the blood, but also by a partial paralysis of the vaso-motor system of nerves. This lowers the "tonus" of the vascular system, the arteries principally, and thereby diminishes intra-arterial pressure, a condition which is always speedily responded to by a reduction in the force and number of the heart's contractions.

A similar effect is produced on the medulla, and its reflex action retarded, so that the number of respirations is diminished, while their volume is generally increased in compensation of such diminution.

Thus we see that the fatigue-producing material, de-

rived from tissue metamorphosis during activity, is the one cause underlying all the various changes in the system observed during natural sleep. It is not so much the want of oxygenation of the brain by the blood, as the want of intra-molecular oxygen, combined with the fatiguing action of the tissue waste accumulated during activity.

The view, also cited by Dr. Hammond, as expressed by Barthez, that: "During sleep there is a *general plethora of the smaller blood-vessels* of the whole body," is probably near the truth. This would apply especially to those organs in which a restitution of the material consumed during activity can only take place during sleep, *i.e.*, brain and muscles in particular. We know that the deposition of the intra-molecular oxygen to be consumed the following day does take place during sleep principally, and it is imperative, therefore, that a fair supply of blood should circulate in these organs. This condition of passive hyperæmia is also one, the production of which is certainly favored by the decrease of intra-vascular pressure. And this gives the key to the apparently anæmic condition of the brain. The cerebro-spinal fluid which pervades the subarachnoidean space and the lymph which fills the perivascular spaces create conditions which must make us careful in diagnosing cerebral anæmia from outward appearances. The production of both is certainly dependent on the intra-vascular pressure to which they simply furnish a passive compensation, and since this pressure is diminished during sleep, the amount of both must also diminish. Although the larger vessels may therefore seem only moderately filled and the bulk of the cerebral mass may apparently be unchanged or even reduced, the small vessels and capillaries must not necessarily be as anæmic as we may be led to conclude from those appearances.

As to the experiment of producing sleep by compression of the carotid, which is held to be corroborating evidence to the theory of cerebral anæmia as the principal cause of sleep, this must be viewed differently in the light of our previous reasoning.

It is not the want of oxygenation to which the causation of sleep thus induced must be ascribed, but to the imperfect removal of the "fatigue-producing" products on the one hand and the additional decrease of intra-vascular pressure, with all its above-described concomitant effects, on the other. The former action is accepted by Dr. Corning himself to a certain extent, since he found "that a *certain degree* of compression of the carotids is much more fruitful in the production of soporific effects toward evening than in the early hours of the morning." He very correctly ascribes it to "an exhausted condition of the ganglia"—although he is not sure whether it is "a cessation of interplasmatic activity due to the collection of debris within the ganglia," or "molecular inertia," or something else; and, furthermore, to a *certain* amount of available explosive energy, hoarded up, which renders the ganglia in a measure independent of the necessity of extensive assimilation from the plastic materials of the blood-stream—at least, *for a time*.

Ranke has acquainted us with the real facts as far as the former—the "fatigue-producers"—are concerned, while Pettenkofer and Voit's experiment teach us that the latter—the "explosive energy"—is due to the intra-molecular oxygen, stored up in the brain tissue during the previous night's rest.

As to the action of a full meal producing drowsiness and sleep, it is evident that this is due to the over-supply of nourishing material to the blood during digestion. The albuminous material being first and quickly attacked in the stomach, its inorganic and extractive matters—the very same "fatigue-producing" substances—first enter the circulation and display their action on the tissues, the brain tissue more particularly, for reasons stated above. The "fatigue" produced induces sleep, in spite of a condition of the vascular system different from that during sleep, following tissue waste by activity, viz.: partial con-

¹The nitrogenous principles, resulting from the decomposition of albuminous matters, have been omitted because they are pretty constant and do not have important physiological effects.

gestion. The latter is due to the increase of intra-vascular pressure caused by the greater amount of blood, and also by the irritation of the sympathetic system, the great splanchnic in particular.

This would show that anæmia is not a necessary requirement for the initiation of sleep, and, therefore, would tend to support the view detailed in the foregoing remarks, viz.: That certain chemical processes are the actual cause of sleep in the manner indicated above. The peculiar action of certain drugs and chemicals to produce fatigue and sleep would add to the evidence adduced in favor of our view.

Progress of Medical Science.

THE ALBUMINURIA OF EPILEPSY.—Dr. Saundby (*London Medical Record*, December 15, 1882), after referring to the contradictory statements of previous observers, says that out of twenty-seven observations of the urine of twenty chronic epileptics, albumen was found on twenty-two occasions. The test employed was simply boiling and acidulating with acetic acid. The quantity varied from a copious precipitate to a faint trace, but as a general rule was small. Five examinations were made directly after a fit; of these albumen was absent in two. He does not regard the albuminuria as having any distinct relation to the fits, but connects it with the age of his patients (the average age being eighteen), the dyspepsia and anæmia which were so common among them, and the fact that the urine was examined after they had been walking. Pulse-tracings were taken in ten cases, but in two only was the tension high.

THE TREATMENT OF DROPSY.—Dr. Leech, in a paper read at the last annual meeting of the British Medical Association (*London Medical Record*, December 15, 1882), discusses the treatment of cardiac, hepatic, and renal dropsy. Firstly, as to the advisability of removing the fluid either by mechanical means or by the eliminants of water, such as diaphoretics, diuretics, and purgatives: every case has to be considered as to the real cause of the dropsy, the stage it has reached, and the condition of the patient and his tissues. For without this the mere routine treatment by eliminants of water may not only not do any good, but actual harm may result. Thus, in the earlier stages of heart-disease with anasarca, diuretics may succeed admirably. Later on, as the general health fails, they lose their power, even though there be no evidence of increasing obstruction of the circulation. And at last it may happen that we cannot drain the water from the oedematous tissues, even when they are pricked or tapped. Secondly, as to the modes of elimination: of these, speaking of paracentesis, Dr. Leech believes that, when dropsy is due to a block in the portal vein, tapping is almost necessarily followed by a recurrence; in acute cirrhosis, when the distention causes great discomfort to the patient, this operation does not give even temporary relief, nor has he seen any good result from it in advanced cases of ascites due to cirrhosis, where symptoms of coma had developed. Diuretics rank next to paracentesis, but they can only act when the kidney is functionally competent, and when the tissues are in such a condition as to be able to give up their water. In hepatic dropsy, copaiba, which can be given for a long time with advantage, and caffeine are most useful. Digitalis and saline diuretics in cardiac, and diaphoretics are of most value in renal, dropsy.

SYPHILIS IN CHILDREN.—In some clinical remarks published in the *Allgem. Wiener Med. Zeitung*, No. 29, 1882, Dr. Widerhofer points out that a child may be (1) born with signs of syphilis, or (2) born dead, or (3) may only show signs of disease during the second or third month after birth. Children born with syphilides show

only the papular or pustular forms. Those in whom signs do not appear for several weeks, usually have the macular form, and this usually develops during the second month. In most cases swelling of the nasal mucous membrane is the first sign of inherited syphilis; the child becomes pale and sleeps badly, and then, some days later, the macular syphilide appears. The spots are most numerous on the face, forehead, outer aspects of the extremities, and on the buttocks. Papules often appear among the maculæ. The pustular is the gravest form of syphilide; it is usually present at birth. When it is limited to the palms and soles, it is called syphilitic pemphigus.

In the diagnosis of a syphilitic rash, polymorphism is the most valuable sign. The swelling of the nasal mucous membrane is also a sign of great diagnostic value. As regards the sequelæ of syphilis, a syphilitic child, as a rule, becomes rickety, and hydrocephalus often follows. The child's nutrition, also, is affected generally; hence the tendency to rickets. Paralysis and lesions of the cellular tissue may also occur, and, after the first year, scrofulous affections. The glandular system is but slightly affected during the early months, and changes in the glands do not occur until the child is a year old. Abscess of the thymus is very rare. The author himself has seen only one case; the child in that instance lived thirty-six hours; but, in five other cases within his knowledge, the children were all born dead. The prognosis of inherited syphilis is favorable as regards life when no signs are present at birth; but much depends on proper management of the diet.

A COMMON MISTAKE CONCERNING CHLORIDE OF POTASSIUM.—It is well known that chlorate of potassium is a very good remedy to gargle the throat, but comparatively few physicians are aware of the fact that it is not this remedy which is so successful in mercurial stomatitis, but chloride of potassium.

Dr. Wertheim draws the attention of physicians especially to this fact. He reminds them that the formula of the first is $KClO_3$, but that of the second KCl . He says that the chlorate should never be used, as in concentrated solution it may even prove very harmful, while the chloride is very innocent; a specific in sore throat, and especially in mercurial sore mouth, and very analogous to common salt, which is simply a chloride of sodium, instead of potassium. In America the chlorate is commonly used; no wonder, therefore, that it is not found here as efficient as in France and Germany, where they use the chloride.—*Medical and Surgical Reporter*.

THE ORGANISMS OF TYPHOID.—Maragliano, of Genoa, has published in the *Centralblatt für die Med. Wissenschaften*, an important note on the uniform occurrence of organisms in the blood of patients suffering from typhoid. He has found them in the blood of the spleen as well as in that of the general circulation. The blood was obtained by means of a hypodermic syringe, the middle of which was passed through the abdominal wall into the substance of the spleen. Dr. Sciamano, of Rome, first showed that blood may be thus obtained from the substance of the spleen during life without any injurious consequences. The blood of the general circulation was taken from the tip of the finger. In each method every precaution was taken to avoid the accidental introduction of organisms. The examination, in this way, of fifteen patients gave the following result: At the height of the disease the blood of the general circulation contains micro-organisms both isolated and grouped. These consist, almost exclusively, of spherical bodies, which have a delicate contour, appear to be homogeneous, and are analogous to micrococci. Some of them are mobile. Similar organisms, again, were seen in the blood of the spleen, and in it, too, were others, rod-shaped, also with delicate outlines, perfectly corresponding to those described by Eberth and Klebs. During convalescence these micro-organisms lessen in number in both the

splenic and systemic blood. When quinine was given to the patient in large doses, the organisms either disappeared from the blood, or were present in it only in small number. The blood from both the finger and the spleen was treated by the method of fractional culture, and a large number of rods were then obtained, similar to those seen in the fresh blood, except that some of them were of greater length. The presence of such organisms in the blood of the spleen after death had been previously established by Sokoloff and Fishel, but Maragliano is the first who has demonstrated their presence in the splenic blood during life. He avoids the expression of any opinion as to their relation to the disease.—*London Lancet*, October 28, 1882.

HEMORRHAGE INTO THE CAVITY OF THE ARACHNOID.

—The subject of hemorrhage into the inter-arachnoid space has been a sorely puzzling one to pathologists. A variety of explanations, more or less plausible, have been put forward to account for its occurrence. But apart from its pathological interest there is also a decidedly practical aspect of the matter. And from a medico-legal point of view the subject may at any time claim our attention. Dr. Morris, in the *Lancet*, November 11, 1882, presents a fair statement of our knowledge on this condition, and his conclusions are to the following effect: 1. That spontaneous effusions into the cavity of the arachnoid—*i.e.*, effusions of blood from disease or excitement—are very often not distinguishable from traumatic effusions. 2. That post-mortem examination does not always explain the cause or the source of the effusion, and that the state of the blood-clot is only a very rough test as to the age of the effusion. 3. Extravasation of blood between the dura mater and bone, as also extravasations beneath the visceral arachnoid, accompanied by brain bruising, are almost certainly traumatic, whether fracture co-exists or not. Extravasations into the substance of the brain and into the ventricles are almost certainly spontaneous when no fracture and no brain bruising co-exists, and are probably so even when fracture without bruising of the cerebral surface is found. 4. Spontaneous effusions may occur without there being any naked eye evidence of disease of the cerebral or meningeal vessels. 5. Spontaneous effusions into the arachnoid cavity from disease or excitement have occurred as early as the twelfth year of life, and at all ages subsequent to puberty. Inter-arachnoid hemorrhage occurs at any age from violence. 6. In slight injuries to the head, such as small scalp wounds without fracture of the skull, or bruising of the surface of the brain, the surgeon should be extremely cautious in attributing inter-arachnoid extravasation to a blow, and more especially when the injured person is of intemperate habits.

THE HOT PACK IN PUERPERAL ECLAMPSIA.—Dr. Brens (*Archiv für Gynäkologie*, vol. xix., 1882) believes that for the cure of puerperal eclampsia either in the puerperium or the last months of pregnancy, active diaphoresis alone, induced by a hot bath, 40° to 45° C., followed by the pack, is all sufficient. The bath must not be prolonged over half an hour, and two to three hours suffices for the envelopment in the pack. This method properly carried out will, according to Brens, also cause oedema and albuminuria to disappear without interruption of pregnancy.

CARDIAC TYPHOID.—M. Bernheim recently read a communication before the French Association for the Advancement of Science upon the cardiac form of typhoid fever (*Progrès Médical*). The author intends to designate by this term cases, in which, without notable organic alteration of the heart, without pulmonary complications, or others capable of explaining the phenomenon, the pulse becomes small, frequent, and depressible. The patient succumbs to this paralytic acceleration of the heart, which may be produced either at the beginning of the fever, with or without concomitant

nervous adynamia, or at a more or less advanced period of its evolution. The axillary temperature may be moderately febrile, normal, or even subnormal. M. Bernheim considers this nervous asystole in typhoid fever to be due to a direct action of the poison or typhoid microbe on the centre of cardiac innervation. In typhoid fever the pulse is usually slower than in other pyrexias, as though the specific poison, like digitalis, had a slowing action on the pulse. It may be conceived that this virus, acting with great energy on the cardiac nervous centre, can produce paralytic acceleration. This theory would also explain the fact noted by the author, that digitalis in these cases is not only inefficacious but dangerous, and that even given as a prophylactic it does not prevent the manifestation of the cardiac phenomena. The author bases his conclusions on the observation of six cases with autopsies. Sudden death in certain cases of typhoid fever where we find no appreciable alteration of the heart, may thus be due to the concentration of the poison upon the cardiac centre. This is the *foudroyante* variety of the cardiac form.

TRICUSPID STENOSIS.—At a recent meeting of the London Pathological Society (*Lancet*, October 21, 1882), Dr. Bedford Fenwick showed a specimen of tricuspid stenosis from a woman aged thirty, who had rheumatic fever at fifteen, and afterward suffered from winter cough and dyspnoea; she went on from bad to worse until admitted into the London Hospital under Dr. S. Fenwick. There was marked distention of jugular veins, but no cyanosis, cardiac dulness very wide to the right, a well-marked presystolic apex thrill and presystolic and systolic apex murmurs; proceeding to the right another presystolic and systolic murmur was detected. At the post-mortem both auricles, but especially the right, were found very much dilated, the ventricles small. The tricuspid and mitral valves were greatly thickened, shortened, and agglutinated together, causing marked stenosis. All the organs were congested. The spleen was during life tender to pressure and pulsated. Cases of this kind were now known not to be very rare. Since his table of forty-six cases he had been able to collect twenty-three more cases, twenty of whom were females, averaging in age 31.7 years. In every case the mitral valve had been more changed than the tricuspid, and in all cases the general health had been good; the great dilatation of the right auricle caused increase of cardiac dulness to the right, and afforded a means of diagnosis.

IODIDE OF LITHIA.—For a long time, the salts of lithia have been considered efficacious in cases of gout. Dr. Kendall has found the iodide by far the most useful of them all. It is most efficacious in cases of actual gout, and may be used with benefit in other cases of a gouty nature. He has known small doses of the iodide to act with benefit in cases of gouty eczema, and in those cases of dyspepsia which may be due to a gouty diathesis the use of this salt is followed by excellent results.—*British Medical Journal*, October 21, 1882.

PAROXYSMAL STERCORACEOUS VOMITING.—Dr. Rosenstein relates the case of a nine year old boy who suffered from peculiar tetanoid seizures, accompanied by unconsciousness, during which the bowels were moved and vomiting of firm brown-colored fecal masses occurred. The attacks came on suddenly during play or in sleep. There was marked opisthotonos with occasional tetanic movements of the arms and legs. After the vomiting the patient complained chiefly of abdominal pains. A cure was obtained by means of injections and the exhibition of large doses of bromide of potassium. The reporter thinks that the condition present was that of a spasmodic stricture of the intestine, from which proceeded strong contractions of the bowel upward and downward, setting up both peristaltic and antiperistaltic movements.—*Centralblatt für Chirurgie*, No. 43, 1882.

COAGULATION OF THE BLOOD.—Dr. Hayem, already well known for his numerous contributions to the physiology and pathology of the blood, has recently published a series of articles in *L'Union Médicale* on the process of coagulation of this fluid. He opposes the theory of A. Schmidt and declares that an increase in the number of white corpuscles stands in no relation to a greater coagulability of the blood. He further states that an anatomical element, the hæmatoblast, is constantly present in the blood and plays the most important rôle in coagulation, the rapidity and degree of this process being in proportion to the number of hæmatoblasts circulating in the fluid. Upon the strength of his last series of experiments Dr. Hayem formulates the following conclusions: 1st, when the blood in fresh sections of vessels retains its fluidity, it is because the hæmatoblasts remain unchanged; 2d, when these bodies become broken up in the plasma, the stagnant blood in the vein coagulates as readily as it would in an open vessel, in spite of the integrity of the walls of the blood-vessel.

ETIOLOGY OF CONGENITAL TALIPES EQUINO-VARUS.—Dr. H. W. Berg advances the following theory of the origin of congenital talipes equino-varus: "In early fetal life the lower extremities look directly backward, and are brought into their normal position by a process of gradual rotation of the thighs. During this process the thighs are flexed strongly upon the trunk, but owing to the extreme outward rotation the legs are retained from full flexion by contact with the abdomen. They cross each other, and the feet lie in the position of marked equino-varus with their soles in contact with the belly of the child. In the process of normal development the rotation inward of the thighs continues, the legs become fully flexed, and the feet turn into a position of strong flexion, their plantar surfaces looking forward and a little outward. But if this process be arrested through any cause, full rotation does not occur and the child is born with talipes."—*Archives of Medicine*, December, 1882.

CARDIAC COMPLICATIONS IN ACUTE ARTICULAR RHEUMATISM IN CHILDREN.—From observations made in a series of cases of acute articular rheumatism in children. Dr. Vohsen (*Wiener Med. Wochenschrift*, November 11, 1882) formulates the following conclusions: 1. In nearly one-half of the cases observed endocarditis occurred and resulted in marked valvular insufficiency. 2. The mitral valve was the one most frequently affected. The endocarditis appeared usually in the first and second weeks of the disease. Pericarditis was also a frequent complication. 3. Salicylate of soda, while it exerted a favorable influence upon the joint affection, seemed not to prevent the cardiac complications. 4. The mild forms of articular rheumatism are especially liable to be followed by cardiac disease, hence a very careful examination of the heart would seem to be necessary in the light cases.

SECRETION OF MUCUS IN THE TRACHEA.—Dr. M. J. Rossbach, upon the occasion of the recent jubilee of the Würzburg University, presented a paper containing the results of his investigations undertaken to determine the physiological laws governing the secretion of mucus in the air-passages. The trachea was opened by a longitudinal incision, and the edges of the wound retracted so as to present an unobstructed view of the mucous membrane. He stated that the secretion of mucus occurred only when the thin film of fluid lining the trachea was so far removed as to permit of irritating influences acting upon the mucous membrane. The mucus itself also protects the underlying membrane by holding the foreign bodies entering with the inspired air. Dr. Rossbach was enabled to obtain the mucus pure and unmixed with pus or saliva. He stated that it was of alkaline reaction, free from albumen, glycogenic ferments, and corpuscular bodies, but containing a large amount of mucine. The secretion of mucus was asserted by him to be indepen-

dent of central nerve-irritation, and to occur when all connection with the central nervous system was severed. The mucous glands either possessed peripheral nerve-centres situated in the membrane itself, or else their action was independent of nervous influences. He also determined in these investigations that vaso-motor fibres pass to the tracheal mucous membrane through the superior and inferior laryngeal nerves, and that the secretion of mucus stands in close relation to local hyperæmia. As to the influence of cold, he found that upon the abstraction of heat from the skin a reflex influence was exerted upon the mucous membrane, finding expression in intense venous congestion. This condition excited a profuse mucous secretion. From this the author concluded that laryngeal and bronchial diseases, occurring after taking cold, might be regarded as due to reflex influences. The occurrence of the death-rattle he attributed to the venous engorgement preceding dissolution. Dr. Rossbach experimented further with a view to ascertain the influence of various therapeutical agents upon the tracheal secretion. He found that alkalies injected into the veins caused anæmia of the mucous membrane and diminished the secretion. Hence they were not to be regarded as expectorants, but as remedies which reduce hyperæmia and thus lead to a cure by overcoming the morbid process. Locally applied, their influence was *nil*. The only exception was in the case of ammonia preparations, which exhibited a local irritant effect. Nitrate of silver diminished the secretion—an effect precisely the opposite of that exerted upon the other mucous membranes. Oil of turpentine, in aqueous solution, increased the amount of secretion, but lessened the hyperæmia. Apomorphia, rue, and pilocarpine excited a profuse mucous secretion, especially the last-named drug, which the author regards as a typical expectorant and prefers to all others. Atropine caused a dryness of the mucous membrane, as also, though in a less degree, did morphine. Combinations of apomorphia and morphia, or of atropia and morphia, according to the indications, the author recommended most strongly. Experiments conducted with the electric current were without result.

TRICHLOROPHENOL.—Dr. Dianin obtains chlorophenysic acid by treating carbolic acid with chloride of lime. This substance is a phenol in which three atoms of hydrogen have been replaced by three atoms of chlorine ($C_6H_2Cl_3OH$). The writer claims the following advantages for it as a disinfectant: 1. The disinfecting properties of trichlorophenol are twenty-five times more powerful than those of carbolic acid. 2. A minute quantity will arrest the most active fermentative processes. 3. It is a powerful antiseptic, far exceeding others in ordinary use—salicylic acid, thymol, carbolic acid, etc. 4. It is a deodorizer as well as a disinfectant. Its own odor may be disguised by oil of lavender (five drops to the ounce). 5. Even when applied in substance it has but slightly irritant properties, and when in solution does not irritate the tissues in the least. 6. The good effects of chlorophenysic acid in soft chancre, diphtheria, etc., the author claims, are indubitable. 7. Every physician can prepare this substance for his own use. 8. The salts possess the same disinfecting properties as trichlorophenol itself. The soda salt is odorless. 9. The lime salt is cheaper than carbolic acid.—*Centralblatt für Klin. Med.*, No. 27, 1882.

A PALATABLE COUGH MIXTURE.—The most elegant and palatable cough mixture ever prescribed by that accomplished therapist, Dr. J. Milner Fothergill, is, he says, the following:

R. Syr. Scillæ.....	3 j.
Acid. hydrobromic. dil.....	3 ss.
Spirits chloroform.....	3 ss.
Aquæ.....	3 j.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, January 20, 1883.

WATER SUPPLY OF NEW YORK CITY.

THE Legislature of the State of New York will probably take immediate action in regard to the various schemes for increasing the water supply of New York City. There are no less than eight plans for effecting this object, and when we state that one suggests bringing water from Paterson, N. J., with an aqueduct to the Palisades, which would have to be tunnelled, and also a tunnel under the North River, some estimate of the many millions of dollars which will be recklessly spent can be made.

One of the most remarkable features of the case appears to be the fact that such an outlay is advised in the face of authentic reports from the public departments that the present supply of water to New York City already exceeds the rational needs of the population, and is even sufficient to meet the demands of increased population for many years to come.

The fault, therefore, appears to lie, not with the quantity of water, but with the methods of distribution, which permit a constant and extravagant waste of probably one-fourth of the whole supply. In view of this circumstance it may well be questioned whether increasing the supply of water would mitigate the evil at present complained of, for if the increase of the waste was to keep pace with increased supply, nothing would be gained.

The practical man, therefore, naturally asks: Is there any method of distributing the water supply of New York City which will give every house all the water it can use, and at the same time cut off the unlimited waste which now exists? We answer that such a method of distribution is in practical use in one of the largest cities in the world, and that the three millions of people in London find it answers all their purposes and satisfies all their wants.

The English plan is to cause every house to provide cisterns to contain the supply of water for their daily use, which are neither limited in number or capacity. Thus every house under this system commands all the water which is required. Water is turned on to these cisterns twice daily in summer, and once daily in winter, when a less supply is necessary; and it is the practice to allow the water to run for some time after the cisterns are filled, which daily flushes out the waste-pipes of every house and the drains in every street.

Londoners pay water-rates according to the number

of cisterns erected in each house, which is an equitable arrangement, and if one tenant wastes all the water in his house, he does not rob his neighbor. Those using large quantities of water *can* also pay water-rate, calculated by a metre, if preferred.

Such a system is connected with pumping the water to create a high pressure throughout the city. This fills the cisterns on the upper floors of every house. No pumping or carrying of water is necessary—an almost unknown comfort and convenience in New York City under the present system.

It may be claimed that the London system involves the placing of cisterns in every house in the city. In reply, it may be said, that the New York system appears also to require the use of cisterns. There is, however, one difference which appears important. The Londoner has his cisterns filled twice daily, without any effort on his part, whereas, except in favored districts, the New Yorker has to perform the agreeable (?) duty of himself pumping the water from the basement to his upper floors.

There may be objections to this plan which we have not presented, and we do not suggest that it is better than to have an unlimited supply from the water mains in the streets; but it appears to meet the requirements of a city having abundance of water for all purposes, which is run to waste in such quantities as to cause inconvenience, and at times a water famine.

We have no desire to discuss the engineering details of the various plans for increasing the water supply, but will offer a few suggestions on the sanitary and hygienic points involved. We trust that any increased supply of water may be drawn from a river source; in such a case the quantity would be without limit, and delivered fresh to the city. It is unnecessary to add that in such a case the water should be drawn at a point beyond the pollution of any city or town.

The analysis of Croton water shows its perfect adaptability for a city supply, and, if sufficiently abundant at all seasons to be delivered direct, it would be the best supply of water supplied to any city in the Union. But the method of storing water in shallow lakes for long periods is an abomination, especially in districts in which fever and malaria are prevalent. Its effect on our Croton water is too often manifest to our sight, taste, and smell, and possibly is often the cause of both fever and malaria in this city.

EPIDERMIC MEDICATION WITH THE OLEATES.

THE "medicinal oleates" and their use in epidermic medication is the subject of a series of articles in the *Ephemeris*.

By epidermic medication is meant the application of remedies to the unbroken skin for the purpose of obtaining local or constitutional effects. "Dermic" medication is a term appropriated by specialists in skin diseases, and "endermic" is to be applied to medication when the cuticle is removed.

The use of various oils and ointments for the introduction of medicines into the system is not a new thing; but we are told that it is only since 1872, when Mr. John Marshall called attention to the value of the oleates of mercury and morphia, that epidermic medication has been systematically attempted. Even now, the observa-

tions that have been made are neither numerous nor scientifically accurate. There are, however, certain striking advantages in the epidermic use of oleates, so that, according to the writer, they deserve a wide trial.

Epidermic medication is based upon the peculiar facility with which the skin absorbs oleic acid and alkaloid salts dissolved in it. This oleic acid is obtained from the "red oil" of the makers of stearin candles. It is an oily liquid of the color of pale sherry, having a peculiar odor and taste, free from acidity. It is thinner than the oils, and has a specific gravity of about .900. Applied to wood, porcelain, or cloth, a greasy spot is made, which lasts as long as a similar spot made with oils or glycerin; but, curiously, when applied to the skin, oleic acid wets it almost like water, and disappears so rapidly that it seems as if it had evaporated.

Oleic acid combines with the various medicinal alkaloids in very large proportions, taking up from 50 to 69.6 per cent. The ordinary oleates, therefore, are weak solutions of oleates of atropia, aconitia, etc., in an excess of oleic acid. In some rare cases where this excess of acid is irritating, a bland oil may be added.

Oleic acid may be made to combine with various metals, such as iron, copper, zinc, lead, mercury, etc. With the exception of the last-named substance, such combinations are not likely to be of much use.

The activity of these oleic acid solutions is best illustrated by the oleate of aconitia. This is a two-per-cent. solution of that alkaloid. Each minim of it weighs eight-tenths of a grain, and contains about one-sixtieth of a grain of aconitia. A drop from the thin lip of a vial is equal to about half a minim (gr. $\frac{1}{120}$) of aconitia. Now, if twice the quantity which the end of the vial's cork will carry be rubbed over half a square inch of skin, a glow of warmth is almost instantly felt. This will disappear in about half an hour. If twice this quantity be applied, there will be prompt tingling in the nerves of the part followed by a sense of heat and prickling and then numbness. The symptoms last for an hour. Such experiments illustrate the potency of the preparation and its mode of use in cases of neuralgia.

Most of the other oleates of the alkaloids are made in the strength of two per cent., *e.g.*, strychnia, veratria, and atropia. They all act with rapidity, though hardly so promptly as the aconitia solution. Five minims of the oleate of atropia applied to the knee-joint produces dilatation of the pupil in a short time. This oleate rubbed upon the skin and covered with oiled silk or gutta-percha tissue acts very much like a good belladonna plaster.

The oleate of morphia is made with a strength of five per cent. Five to ten minims applied to the abdomen and covered with oiled silk is the usual dose for children of one to four years. There is considerable evidence that opium acts very well administered in this way, producing very little constipation or gastric disturbance.

The oleate of quinia contains, or should contain, about twenty-five per cent. of quinia in solution. A fluidrachm would contain about seventeen grains (gr. xvij.) of the salt. The preparation may be used hypodermically or epidermically. In the latter case as much as two drachms must be rubbed in at a time, and it should be covered with oiled silk. A person can get the tonic ef-

fects of the quinine by rubbing the oleate upon himself morning and night.

The epidermic medication by the use of oleates evidently deserves attention, if only to determine the limits of its usefulness. The skin is normally a protective, not an absorbing organ, and it can never be depended upon as a medium of medication like the *primæ viæ*; but it can, no doubt, be utilized more often than is now done, and to the saving of more delicate tissues.

WOUNDS IN THE COURSE OF DIABETES.

THE recent death of Gambetta, who was reported to have been a sufferer from glycosuria, revives the interest in the question of operations in diabetes. That wounds occurring in diabetic patients are prone to resist treatment, and to be followed by phlegmonous inflammation, has long been known. The frequent occurrence of gangrene and unhealthy inflammatory processes in such cases was first observed by a French military surgeon, Marchal de Calvi, in 1853. Ten years later, he had already collected a series of one hundred and thirty-three illustrative cases. He made the observation that it was generally the otherwise healthy and robust-looking patients, and especially those of middle age, who were most frequently affected in this way.

Nélaton and Verneuil, and, later, Peyrot, have also recorded corroborative cases. In Germany, Wagner and Griesinger, have in turn discussed the subject. More recently, a work by Dr. Roser has appeared, in which he states his conviction that the development of inflammatory processes, in the course of diabetes, is due wholly and solely to the altered condition of the blood. He believes the gangrenous and phlegmonous processes to be entirely different from those of the non-diabetic, being altogether independent of the possible entry of septic germs from without. Hence antiseptic treatment is not sufficient alone to ward off septic inflammation. Only when coupled with strict antidiabetic diet is it of any real value.

Other German writers, as Kraske and König, believe, however, that the infection takes place from without. But they affirm that the condition of the blood in diabetes is especially favorable to the further development of the morbid processes. Indeed, it is often favorable to such an extent that antiseptic treatment is of no avail.

Still more recently, Dr. Müller has given his attention to this subject (*Aerztliches Intelligenzblatt*, No. 41, 1882). From the consideration of a large number of cases, collected from various sources, he finds that strict antidiabetic rules of diet are of the utmost importance. Indeed, the antidiabetic treatment is far more conducive to the healing of the wound than the antiseptic treatment of the wound itself.

The author's paper suggests once more the question, whether operations ought to be undertaken upon diabetic patients or not. The opinions of Marchal, Verneuil, and Roser may be accepted in answer. They all agree that operations should never be performed in such cases unless they are absolutely necessary; and only then if some improvement has been found to follow upon a course of dietetic treatment, and if the patient be otherwise in fair health. Careful dieting, therefore, should

invariably be enforced both before and after the operation.

In view of such unequivocal testimony we may well question the propriety of recent German strictures upon the treatment which Gambetta received at the hands of his attending physicians and surgeons. The spirit that prompts such utterances as those of Dr. P. Niemeyer (who, it will be remembered, directly accused Gambetta's physicians of indirectly causing his death by unduly postponing an operation) cannot be too severely censured.

THE KINGSTON MEDICAL SCHOOL AND MEDICAL CO-EDUCATION.

An event occurred at the Kingston Medical School, not long ago, which furnishes an unpleasant picture of medical students and medical education in Canada. The Kingston Medical College some time ago organized a course of lectures for female students. Matters went on smoothly enough until December last, when the lecturer on physiology touched upon the subject of castration. His remarks were received with cheers and stamping, all eyes being turned on the seven female students present. The latter finally left the room in a body and complained to the Faculty. The male students held an indignation meeting and sent a memorial to the Faculty, which was offensive in tone, and which ended with the declaration that, unless the female students left, the male students would go themselves. The Faculty, very properly, refused to be dictated to. But while a discussion was going on, the Trinity Medical School, at Toronto, made an offer to take the Kingston students who had already paid their dues for nothing, and the rest for half-price! This forced the Kingston Faculty to yield to the demands of the students.

If the above account of the affair, which we take from the *Canadian Practitioner*, be true, and there is no reason to doubt it, invective is hardly strong enough to fitly characterize the action of the Trinity School. To take advantage of another's distress, to strike a man when he is fallen, is considered by honest men as the last excess of infamy. Unless this Trinity College can explain itself, it will always have the flavor of carrion about it in American nostrils.

The dean of this school, to be sure, says that the Faculty thought that the Kingston medical students had entirely withdrawn from their school. But it is not explained why credit was offered for lectures of which certificates were refused by the professors, or why their offer was made with such haste and such absence of consideration for a sister Faculty.

The affair is a serious drawback to medical co-education in Canada.

THE HOSPITAL SATURDAY AND SUNDAY COLLECTION.

It is very evident that the Hospital Saturday and Sunday movement is not responded to by the public in a degree that corresponds with its merits. The sum collected this year, up to January 15th, was only \$26,354.92, out of which about \$1,200 is to be taken for expenses. Further sums are expected, but it does not seem possible to reach even the sum contributed last year, which was about \$40,000.

This is in marked contrast to the collections made in London, which amounted in 1881 to \$170,730, this sum being contributed by 1,338 congregations.

There is in London a much more hearty co-operation of the churches than in New York. The Catholics unite in the work there, but do not do so here. A very extraordinary indifference was shown by Protestant churches also. Thus, of 38 Baptist churches only 1 responded; of 21 Lutheran churches none; of 55 Methodist, only 4; of 50 Presbyterian, only 5; of 71 Protestant Episcopal, only 43; and of 20 Reformed Dutch churches, only 5.

News of the Week.

KINGS COUNTY MEDICAL SOCIETY ON THE INSTRUCTION TO DELEGATES.—At the meeting of the Kings County (N. Y.) Medical Society held on Tuesday evening, January 16th, the resolution instructing the delegates to the State Medical Society to vote for the old Code was rescinded by 49 to 26. Dr. Lewis S. Pilcher, an avowed opponent of the old Code, was elected as one of the delegates to fill a vacancy.

TARIFF ON QUININE AND CINCHONIDIA.—It is reported that the Committee on Ways and Means have stricken quinine and cinchonidia off the free list.

THE PENSION BILL was passed by Congress January 13th. The following are some of the items: For army pensions, \$80,000,000; for navy pensions, \$1,000,000. Fees and expenses for examining surgeons, \$275,000. The allowance of from \$12 to \$35 per month is made for the loss of an eye, and \$50 per month for both eyes, while the loss of hearing is estimated at \$25 per month.

MORE BODY-SNATCHING IN MONTREAL, CANADA.—Four bodies stolen from the cemetery at St. Martine, have been discovered, packed in boxes, in St. Jean Baptiste village. They were duly returned to their vaults. No arrest has yet been made.

CEREBRO-SPINAL MENINGITIS IN INDIANA.—Spotted fever prevails in Rush County, Ind.

CARE OF THE INSANE IN WISCONSIN.—Governor Jeremiah M. Rusk, of Wisconsin, in his annual message, January 11th, calls attention to the necessity of caring for the insane in properly equipped State hospitals, and strenuously advises against the employment of jails and almshouses as asylums.

COW-POX IN BALTIMORE COUNTY.—Spontaneous cow-pox is said to have broken out in a herd of Alderney cattle in Baltimore County, Md.

DR. D. W. BUTLER, of Connerville, Md., injured by the cars on Saturday last, is reported in a critical condition from supposed internal injuries.

SCARLET FEVER prevails as an epidemic in Walla Walla, I. T.

BURNING OF A SMALL-POX HOSPITAL.—The Sailors' Small-pox Hospital, near Crisfield, Md., was destroyed January 13th, by fire, caused by the upsetting of a kerosene lamp by a delirious patient. The latter subsequently died from exposure. No other lives were lost.

THE DISPENSARY FOR NERVOUS DISEASES in Baltimore, under the charge of Dr. John Van Bibber, is reported to be a thousand dollars ahead of its expenses during the past year. The small fee system appears to explain the result.

STEAM-HEATING AND FOUL ODORS.—Some of the business men in the lower part of the city have complained of foul odors which arise from the steam-heating pipes. The Health authorities have found that in laying the pipes gas has been liberated from the saturated ground, and that the composition of tar and other materials with which the pipes have been covered also give out a sickening smell when heated.

A BABY-SHOW IN HAMBURG, on the American plan, is about to be inaugurated under very promising auspices.

MUTUAL AID SOCIETIES IN VIENNA AND ST. PETERSBURG.—At Vienna and St. Petersburg Physicians' Mutual Aid Societies have at length been organized.

THE PHILADELPHIA COUNTY MEDICAL SOCIETY.—The Philadelphia County Medical Society has elected its officers for 1883. They are: *President*, Dr. William M. Welch; *Vice-Presidents*, Dr. W. R. D. Blackwood and Dr. A. Hewson; *Secretary*, Dr. Henry Leffmann; *Treasurer*, Dr. Louis K. Baldwin. This society has about four hundred members, and with three meetings every month accomplishes a great deal of work. As it is the only body competent to send delegates to the Medical Society of the State of Pennsylvania and to the American Medical Association, it includes in its membership nearly all the active medical men of the city.

POLICLINIC IN BALTIMORE.—Following the example of New York and Philadelphia, a Policlinic is to be established in Baltimore.

FIRST AID SOCIETY.—The Police and Fire Commissioners respectively recommend the members of their forces to attend the lectures given by the First Aid Society.

A LIBERAL DONATION TO THE GERMAN DISPENSARY.—It is rumored that Mrs. Oswald Ottendorfer, a wealthy German lady of New York, has donated one hundred thousand dollars to the German Dispensary of this city. This will materially increase the usefulness of this thriving institution, by enabling its managers to obtain a larger building, which is much needed.

FEES FOR LEGAL SERVICES TO GOVERNMENT.—Over seventy thousand dollars have already been paid for extra legal services in the Star Route case, and the end is not yet. How does this sum compare with the beggarly amount that was paid the physicians who so faithfully attended the late President Garfield. Is there no committee sufficiently competent, before whom these legal claims can be brought for proper adjustment regarding true value received?

THE ASSEMBLY STANDING COMMITTEES.—The appointments to the following committees will be of more or less interest to members of the medical profession throughout the State:

Public Health.—Messrs. Nelson of Cortland, Delehanty of Albany, Craig of Steuben, Sheridan of Kings, Murray of Fulton and Hamilton, Roesch of New York, Mullaly of New York, Derrick of Rensselaer, Benjamin of Steuben, Wertelman of New York, and Mulholland of Kings.

State Charitable Institutions.—Messrs. Bartlett of Broome, Odell of Orange, Roesch of New York, Burns of Kings, Emans of Dutchess, Nelson of Cortland, Benedict of Ulster, Page of Wyoming, and Geddes of Onondaga.

General Laws.—Messrs. Townsend of Oneida, Searl of Steuben, Burns of Kings, Higgins of Niagara, Snyder of Schoharie, Wilcox of Erie, Quinn of New York, Armstrong of Washington, Boynton of Essex, Cleveland of Yates, and Brooks of Putnam.

THE NATIONAL ASSOCIATION FOR THE PROTECTION OF THE INSANE AND THE PREVENTION OF INSANITY holds its annual meeting in Philadelphia, on January 25th, at the College of Physicians. There will be an afternoon and evening session. The Address of Welcome will be delivered by Samuel D. Gross, M.D. The following papers will be read: "Functions of the Medical Staff of an Insane Hospital," by Prof. Traill Green, M.D., of Easton, Pa.; "Preventable Causes of Insanity," by Dr. J. S. Jewell, of Chicago; "How to Protect the Insane," by Dr. Joseph Parrish, of Burlington, N. J.; "The Duty of Medical Colleges and the General Practitioner toward Mental and Nervous Diseases," by Dr. C. K. Mills, of Philadelphia; "Obligations of the Sane toward the Insane," by Rev. R. Heber Newton; "The Prevention of Insanity in Certain Cases of Nervous and Hysterical Women," by Dr. H. Marion Sims; "The Legal Rights of the Insane," by Clark Bell, Esq., of New York; "The Prevention of Insanity by the Rational Treatment of Inebriety," by Dr. T. D. Crothers, of Hartford, Ct. Remarks will be made by Hon. H. M. Hoyt, ex-Governor of Pennsylvania.

A NEW ANATOMY ACT FOR PENNSYLVANIA.—The Anatomists' Association of Philadelphia expects to have a new Anatomy bill introduced during the present session of the Pennsylvania Legislature. This bill will give the unclaimed bodies of all counties to the profession for scientific investigation and for educational purposes. At present the Philadelphia colleges, with their hundreds of students, have no legal supply except from the city of Philadelphia; yet the colleges advertise for students, claiming to have an abundant supply of material. The inertia of these institutions, since the imperfect Anatomy Act of 1867 was passed, is remarkable. The Philadelphia County Medical Society has opened a correspondence with all other county societies in the State, requesting co-operation in an endeavor to have the new bill passed. Unless petty jealousies weaken the force of the movement, the united force of the profession will be able to accomplish much good at Harrisburg.

A BILL TO PROVIDE FOR THE PROPER INCARCERATION OF LUNATICS has been presented in Assembly by Mr. Hodges, of Brooklyn. It provides that no person shall be confined as a lunatic without first having been tried by a jury before a Court of Record.

PASTEUR announced at the meeting of the Academy des Sciences that 85,000 sheep had been inoculated for anthrax. The mortality from this disease had fallen from 9 per cent. to 0.75 in consequence.

JOURNALISTIC CHANGES FOR THE YEAR.—There are few new medical journals this year, but a good many changes in the old ones. Our wide-awake and interesting contemporary, *The Michigan Medical News*, has consolidated with *The Detroit Clinic*. The combination is to be called *The Medical Age*, and is to be published by Mr. G. S. Davis. We are glad to learn that Dr. Mulheron is to continue as managing editor. *The Rocky Mountain Medical Times* has chosen a less rugged title, and appears as *The Denver Medical Times*, Dr. F. Marquand Trask being added to the editorial staff. *The Canadian Journal of Medical Science* has become *The Canadian Practitioner*. *The Sanitarian* has become a weekly. It is published in quarto form, double column, sixteen pages. Dr. S. N. Bell continues as editor, and Dr. T. P. Corbally as associate. The journal has secured a large list of collaborators, including many of the prominent sanitarians of the country. *The Sanitary News* is a new weekly recently started in Chicago. *The Independent Practitioner* starts out with a new editorial staff consisting of Dr. Leigh H. Hunt and W. C. Barrett, D.D.S., M.D. *The Planet* is the title of a new monthly medical journal published in New York, and edited by Dr. C. E. Nelson. Contrary to what its title indicates, it will not shine by reflected light, but will contain only original articles. *The American Medical Bi-Weekly* has become *The American Medical Weekly*, and under its experienced editor will doubtless continue to take a front rank in medical journals.

ALUMINIUM.—The recent discovery of a process by which aluminium can be manufactured cheaply in large quantities has created much excitement. It will be well for ingenious members of the medical profession to remember the properties of this metal. Aluminium is a white metal having a somewhat bluish lustre when polished. It is very malleable and ductile, yet very tough, and is about as light as glass or porcelain. It is very sonorous, and an excellent conductor of heat and electricity. It is unaltered by exposure to air—even moist air. It is not attacked by nitric or sulphuric acids, but hydrochloric acid rapidly dissolves it. It has been chiefly used in the arts as an alloy for making bronzes, etc.

THE BELLEVUE TRAINING-SCHOOL FOR NURSES held its tenth annual meeting last week, and gave diplomas to twenty nurses. There have now been graduated one hundred and sixty-eight in all. Three of these have recently gone to Italy to establish a training-school in Rome.

A STATE BOARD OF PHARMACY.—At the meeting of the Erie County Medical Society, T. M. Johnson, the President, delivered an address in which he urged the necessity for the creation of a State Board of Pharmacy. The Counties of New York and Kings now have laws regulating pharmacy, but in the other counties almost any one may sell drugs and poisons. A bill will be sent to the Legislature for the correction of this state of things.

SMALL-POX.—Small-pox is on the increase in Baltimore, Montreal, Atlanta, Roanoke County, Va., and in different parts of Kentucky.

REGULATING PHARMACY IN PENNSYLVANIA.—A bill has been introduced in the Pennsylvania Legislature for the purpose of regulating the practice of pharmacy, the sale of poisons, and preventing adulterations.

SURGEON-GENERAL OF MASSACHUSETTS.—Dr. O. G. Cilley, of Boston, has been appointed Surgeon-General on General Butler's staff.

DR. EBENEZER DEARBORN, of Nashua, New Hampshire, one of the oldest physicians in the State, died on Monday, aged ninety years.

DEATH OF SAMUEL A. MUDD.—Dr. Samuel A. Mudd, the physician who set the leg of Wilkes Booth, the assassin of President Lincoln, died on Wednesday, at Bryantown, Charles County, Maryland. He was fifty years old, a member of an old Maryland family.

DR. E. MUSSEY HARTWELL has been selected instructor of the proposed gymnasium for the muscular development of the students at the Johns Hopkins University. On January 10th he introduced his course of lectures by one on "The Development of the Human Body." A large audience was present.

THE FLORIDA MEDICAL ASSOCIATION held its annual session at Jacksonville, on the 16th.

BITTEN BY A SQUIRREL.—Dr. W. G. Stedman, of Southington, Conn., was bitten last week in the hand by a pet squirrel; severe lymphangitis ensued, and it was feared he would lose his arm.

BAD WATER IN PHILADELPHIA.—The drinking-water of Philadelphia is reported to be unwholesome.

SUIT FOR LIBEL BY A PHYSICIAN.—Dr. William A. McDonald, of Lynn, Mass., has sued a Roman Catholic priest of that place for libel. It is claimed that the latter charged the physician with being unskilful and advised persons not to employ him.

STRICKEN WITH HEMIPLEGIA.—Dr. Samuel R. Rixey, a prominent physician of Culpepper Court House, Va., has been stricken with hemiplegia.

PROSECUTION OF DRUGGISTS FOR PRACTISING MEDICINE.—Several druggists in Quebec are to be prosecuted for practising medicine without licenses.

EAST RIVER MEDICAL ASSOCIATION.—An interesting paper was read before the East River Medical Association last evening, at the house of Professor J. D. Bryant, by James R. Taylor, M.D. Subject, "The Fractures of the Long Bones." The doctor had quite a number of well-executed engravings prepared expressly to illustrate his views, which were distributed during the reading. He also exhibited several entirely original mechanico-surgical appliances, which he uses in his practice. The paper was well received by those present, and generally endorsed as a valuable contribution to the literature of the subject.

AMERICAN PORK.—The authorities at Berlin are discussing the propriety of prohibiting the importation of American pork, which is said to be largely infected with trichinae.

Reviews and Notices.

MICROSCOPICAL MORPHOLOGY OF THE ANIMAL BODY IN HEALTH AND DISEASE. By C. HEITZMANN, M.D., late Lecturer on Morbid Anatomy at the University in Vienna, Austria. With 380 original engravings. 8vo, pp. 849. New York: J. H. Vail & Co. 1883.

UNDER the above title Dr. Heitzmann has collected and published some twenty-two chapters of varied matter, intended to be illustrative of the experience acquired by "ten years' intense labor." A more curious medley of strange assertions, premature conclusions, and extravagant theories it has rarely been our lot to peruse. At times we feel constrained to believe that the author is merely an artful satirist, so keen and rich is the quality of his humor. But there are other passages in the book that present the stolid front of undisputed and indisputable fact, where real science is not made to blush in the presence of pseudo-scientific posing.

Dr. Heitzmann evidently felt unequal to the task of writing single-handed so great a work on microscopy. He has accordingly secured the invaluable collaboration of such well-known histologists as Schöney, Hassloch, Hoeber, Elsberg, Tauszky, Frankl, Müller, Johnstone, and other eminent scientists. It is perhaps not surprising, therefore, that the result achieved by the combined efforts of so many able and competent observers should be in many respects a truly brilliant one.

The preface is a masterpiece in its way. It must be read and studied from beginning to end, in order to be fully appreciated. Dr. Heitzmann, it should be remembered, scored a brilliant fiasco in Europe as regards the recognition of his flights of fancy. But then he informs us that "European microscopists are, to a great extent, prejudiced by the teachings of the older masters." The new master has "received in New York much encouragement from students and co-workers." He has also "been magnanimously supported by a friend, who is not a medical man, but a prince in character and wealth, and who surpasses most European princes in that he will not allow me (Heitzmann) to inscribe his name upon the dedicatory page." But in addition to this interesting, important, and withal graceful personal explanation, "The United States," we are told, "are ahead whenever new ideas of practical importance are to be acknowledged." Now, as regards histology, America is ever ready to concede to Europe a well-earned pre-eminence. Moreover, even America is by no means prepared to accept Heitzmann's morphological vagaries as the gospel of scientific truth in microscopy.

Most of the articles in this volume have already appeared elsewhere, and not a few are translations of papers published in German years ago. In all essential features, the author still adheres to his former peculiar views on protoplasm, or, as he now prefers to call it, "bioplasson." But the network of living matter, which he holds to be the morphological foundation of all animal life, is by the vast majority of competent microscopists accepted only as the reticulum of cellular death.

It may not be amiss to illustrate by a few quotations the author's style and some of his hasty assertions. Tearing and teasing of tissues he utterly condemns as a most objectionable method of preparation. All working histologists know, however, that it is an indispensable procedure for many examinations, and that perhaps no other single method has yielded so many and such practical results as this one. Glycerine is the only liquid which he fully recommends for permanent mounting. This again runs counter to universal experience, which has found in the various balsams the best means for permanent mounting. Glycerine is of special value for hasty and temporary mountings. In this connection Heitzmann also writes (p. 81) as follows: "The process of mounting in glycerine is simpler and easier than any

other method, and, if all precautions mentioned are carried out with care, no change," etc. "True glycerine specimens need more careful handling than balsam specimens." The contradiction contained in these statements is apparent at once. "Ammoniacal carmine solution is the most satisfactory for staining specimens obtained after hardening in chromic acid." Most histologists have found hæmatoxylin, eosine, and other dyes far superior to carmine for chromic acid specimens. "After Elsberg's at present almost generally adopted designation, we shall term the molecules of the living matter 'plastidules'" (p. 13). So far from being generally adopted, Elsberg's designation is as little known as his competency as a histologist is widely recognized. On page 17 this well-known laryngologist is also preferred to Darwin and Hæckel as a successful theorist on protoplasm. And here we may mention that although Heitzmann repeatedly asserts that he has discarded the term protoplasm altogether, he almost constantly employs it throughout the volume.

By looking at a pus-corpuscle Heitzmann is able to tell "whether the person from whom the pus comes is healthy and strong, or weakened by chronic disease, as tuberculosis" (p. 32). We doubt whether any conscientious histologist would dare to imitate this wild feat. But in hundreds of such examinations (p. 59) Heitzmann has diagnosed constitutional conditions from the appearance of the network in leucocytes. And as he modestly adds, "I was right in every instance; not one mistake has occurred." And again, "To-day my hopes have turned into accomplished facts," meaning his pus-corpuscular hopes, expressed some three years ago. "Thus I have arrived at a point of perfection which allows me to tell the constitution of a person without knowing anything of his former life" (p. 60). "The bioplasson is one uninterrupted mass throughout the body, and is connected from the top of the head to the heels, in what we call tissues" (p. 61). "The animal body, as a whole, is one protoplasmic mass, in which are imbedded a relatively small number of isolated protoplasmic corpuscles, and various other non-living substances" (p. 131). Now all this uninterrupted mass strikes us rather as an uninterrupted and unmitigated mess. Moreover, it is the veriest physiological heresy to assert that the healthy normal body contains dead ingredients in a morphological sense. All non-living particles would necessarily act as foreign bodies in healthy tissues or organs. On page 135 we learn that the "cell-theory had to be abandoned in the light of my investigations." As a matter of fact this theory is still largely dominant, and certainly no more acceptable explanation of various histological and pathological phenomena has yet been advanced. Biologists will doubtless be pleased to know that "on cartilage-tissue have mainly rested, for the last forty years, our biological views" (p. 141).

It is clearly impossible, within the limits of the present notice, to particularize more fully the numerous extravagant notions and eccentricities contained in the pages of the work before us. One is surprised also at the spirit in which it is conceived and written. For nobody can fail to read between the lines the bid for laboratory students, and the too evident desire at self-advertisement. Witness only the following selections: "A few months'—nay, a few weeks'—thorough study under the direction of a reliable teacher will suffice to enable every one to see what really can be seen in the plastids," etc. (p. 60); "Life insurance should be based upon microscopical examination" (p. 61); "Marriages should be allowed in doubtful (?) cases only upon the permit of a reliable microscopist" (p. 61); "Many examinations, etc., have enabled me to reach a certain degree of positiveness in the diagnosis of the diseases of the genito-urinary tract. The microscopic analysis of the urine also requires a thorough study, which, however, is greatly facilitated by the guidance of a reliable and experienced teacher."

In justice to the author it must be said that his work

is not without redeeming features. Many of the drawings are beautifully executed, and cannot fail to be admired. Practical suggestions as to methods of preparation are found among others which are the reverse of this. Although no attempt at a systematic presentation of the facts of normal and pathological histology has been made, nevertheless scarcely a living issue in these branches is left untouched. Here and there some really valuable expression of opinion may be found—valuable rather in its stimulating further thought and study than in direct worth. In their present status Heitzmann's notions may be likened to some turbid solution, in which time and calm repose may yet allow the formation of clear crystals representing scientific thought and truth. It is to be hoped that this much-needed time and repose may be given before a second edition of Heitzmann's book appears.

THE PHARMACOPŒIA OF THE UNITED STATES OF AMERICA. Sixth Decennial Revision, by Authority of the National Convention for Revising the Pharmacopœia held at Washington, A.D. 1880. New York: Wm. Wood & Co. 1882.

IN most civilized countries, the necessity for some standard as to the quality and preparation of drugs that are in use by the profession, has led to the publication of some work that may be regarded as the authoritative exposition of this standard. In most European countries the government gives the necessary authority for the preparation of the work, which, when published, receives the name of *The Pharmacopœia*. In America, however, the Federal Government does not itself possess the power to authorize the publication of such a work, this power pertaining to the respective States. If, however, each State should establish its own Pharmacopœia, inevitable confusion would result. To obviate this, a plan was devised fifty years ago, and has been in successful operation ever since. Every ten years a convention is held in Washington, which convention is composed of representatives appointed by the several State societies, medical colleges, and pharmaceutical associations. The last convention was held in May, 1880, at which time a general plan for revising the pharmacopœia was agreed on, and a committee, consisting of twenty-five physicians and pharmacists was appointed to carry it out. This committee were well known in their respective professions, and well qualified for the special task before them. On examining the list we find all sections of the country represented, Massachusetts and New York at the East and North, North Carolina and Missouri at the South and West. The committee devoted a little more than two years to the work of revision, and the result of their labors is now before us. On examining the work we are at once struck with the important differences that exist between it and its predecessors.

The previous Pharmacopœias were mere skeleton works, of comparatively little use to pharmacists, and of still less utility to physicians. As a consequence, it was rarely met with in the libraries of the latter. The new Pharmacopœia, on the other hand, is indispensable to druggists, and is at the same time one of the most practically useful books of reference with which we are acquainted. The arrangement of its contents is alphabetical, and under the name of each crude drug we find a list of its official preparations. Under each drug we also find a very complete description of its physical appearances, so that it may be readily recognized and distinguished from spurious and adulterated articles, chemical tests being given where necessary. A large number of obsolete drugs and preparations have been dropped, and about an equal number of new ones have been added, as well as several entirely new processes for their preparation. Among these latter we notice abstracts, triturations, tinctures of fresh plants, etc. Abstracts are milk sugar preparations, each grain of which represents two grains of the crude drug. Triturations, on the other hand, possess one-tenth the strength of the original. The former

are well adapted to the dispensing of belladonna, digitalis, etc., while the latter render the dispensing of the stronger alkaloids, etc., more safe and accurate, and will prove useful in prescribing some of the metallic salts. In many cases patients find it more convenient to have their medicine in a dry or solid form, that can readily be carried about the person. Especially when travelling is the ordinary bottle medicine a nuisance, and many are averse to the old-fashioned pill. These two preparations in powder form are likely to become popular with patients, even if they are slow of adoption by physicians. We note that the strength of some of the preparations varies a little from the former Pharmacopœia—notably in the case of the fluid extracts, which are about five per cent. weaker, a difference of three or four drops to the teaspoonful. The opium preparations will be somewhat stronger, but at the same time more uniform.

The arsenical solutions have a uniform strength of one per cent.

As a rule the formulæ are indicated in parts by weight, as in most of the Continental Pharmacopœias; in the case of pills, however, absolute weights are used, and a *double* formula—troy and metric—is given, the result in either case being the same.

There are a few changes in the nomenclature that it would be well for the careful prescriber to familiarize himself with.

Many useful tables will be found at the end of the volume—such as a table of elementary substances, with their symbols, atomic weight, and equivalents; a table of thermometric equivalents according to the Centigrade and Fahrenheit scales; tables of percentage and specific gravity, including alcohol, acetic acid, hydrobromic acid, hydrochloric acid, nitric acid, sulphuric acid, phosphoric acid, etc.; a table of the solubility of chemicals in water and in alcohol, and saturation tables. There is a list of articles added to the pharmacopœia and one of those dismissed from it; lists of changes of official Latin and of official English titles; a table exhibiting differences of strength of the preparations, as made according to the last and the present pharmacopœia; and, finally, tables of weights and measures.

If once on the physician's table, this work will probably be more frequently consulted as an aid to prescribing than any other book in his library, for it represents the results of the latest scientific researches. The committee who had this work in hand deserve great credit for bringing the work up to the present needs of the profession.

Owing to the alphabetical arrangement of the articles, described the work will be found to be exceedingly convenient for reference, and in addition there is a very complete index appended to the volume. It is issued in capital style.

BARBERS' BASINS AND SEWER-GAS.—A new danger has been discovered by the *Lancet*, a danger of breathing sewer-gas from the waste-pipes of barbers' basins, when being shampooed. The danger is the more serious because the whiff of germ-laden gas would pass unnoticed among the scents and sweet odors of the barber shop, and the unconscious victim while breathing rose and jasmine, would also be absorbing the bacteria of various diseases. Probably the basins of the average barber shop are no better plumbed than other fixtures are, untrapped wastes and syphoned traps may make as many open connections with the drain as are found in the average of other buildings, but, on the whole, we regret that the *Lancet* has directed attention to this subject, because it gives opportunity to the barber to ask the man in the chair to take one more article than is on the list now. When the present category of oils and scents, bay rum and hair reviver is gone through there will hereafter remain the inquiry, whether the m. c. will not take a little disinfectant through an atomizer? On behalf of the shaved community we protest.—*Sanitary Engineer*, November 23, 1882.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, December 27, 1882.

GEORGE L. PEABODY, M.D., VICE-PRESIDENT, IN THE CHAIR.

REPORT OF THE COMMITTEE ON MICROSCOPY.

DR. W. R. BIRDSALL, of the Committee on Microscopy, reported that they had examined the microscopic sections of the tumor presented by Dr. Ferguson, and sustained his report, which is herewith submitted:

"CARCINOMA OF THE FUNDUS UTERI.

"Almost the entire fundus of the uterus is occupied by a soft tumor, nearly pear-shaped, the antero-posterior diameter of which is one and three-fourths, and the vertical diameter three and one-fourth inches. From its base of attachment at the fundus it extends downward, polypoid in form, distending the body and neck of the uterus, and presenting by a blunt terminus at the external os. This projecting portion of the tumor is constricted circularly, the constriction corresponding to the internal os. The consistency of the tumor is uniform throughout, and both its consistency and appearance are characteristic of a medullary carcinoma.

"The examination of sections made from different parts of the tumor, especially regions of most recent origin, shows it to be composed of epithelial cells and a connective tissue stroma.

"The alveolar arrangement of this stroma is characteristic of carcinoma, the alveoli differing in size and shape.

"The alveolar walls vary much in thickness, and contain numerous young cells and few connective tissue nuclei.

"Certain areas in the interior of the tumor have undergone retrograde changes.

"In places throughout the tumor are seen limited areas of uterine tissue, in which the morbid growth was developed.

"The cells which fill the alveoli differ in different places; they are large cuboidal or low cylindrical cells, where they line the walls which limit the alveoli. They are smaller in the centres of the alveoli, where they are irregular in shape. Each cell is furnished with a distinct large nucleus.

"The tissue of the tumor is not very vascular, but it is worthy of note that the tissue of the uterus in the neighborhood of the growth is much more bountifully supplied with blood-vessels than the uterus elsewhere, or than the normal non-pregnant uterus.

"(Signed) F. FERGUSON."

DR. W. H. PORTER suggested that this growth, which now presents the characteristics of a carcinoma, probably originated in a papilloma, the alveolar appearance representing the remains of the former interpapillary spaces.

The vaginal tumor presented by Dr. Tauszky at the stated meeting, November 22, 1882, showed, on section, an abundant development of apparently new epithelial corpuscles, with many bundles of fibrillated connective tissue. At one point there were large cells, with smaller ones arranged in a concentric manner around the large central cells, but no well-developed epithelial nests were seen. The growth, however, presented a suspicious appearance, although there was no positive evidence that it was an epithelioma.

CANCER OF THE OMENTUM, MESENTERY, PANCREAS, AND STOMACH.

DR. VANGIESON presented the liver, the kidneys, the spleen, the pancreas, a portion of the small intestines, with the mesentery, and the right lung removed from the

body of a man who, when he first saw him, was sitting in a chair and had evidently been a great sufferer for a long time. He was sitting with his head leaning forward and occupying the position usually assumed when suffering from great dyspnoea. His dyspnoea was extreme, but it was somewhat relieved by inhalations of nitrite of amyl. The patient died on December 19th and the autopsy was made on the 21st. Dr. VanGieson learned that the man had, for three years, been more or less an invalid. For a long time he was treated for dyspepsia without relief, and for the last year he had been compelled to remain at home at least three or four days each week from his work. His occupation was that of a turner, and during his business he was accustomed to press his abdomen against the material on which he was at work. The entire history of the case was that of one in which the patient had suffered from some form of malignant disease of the abdominal organs. Dr. Joseph Hilton, of New York, was the last of many physicians who saw him, and was the one who first made a correct diagnosis. A somewhat remarkable feature of the clinical history was oedema of the right arm and left leg, while the left arm and right leg were unaffected. At the autopsy the omentum was found filled with carcinomatous growth, also the intestine and mesentery was studded with numerous cancerous nodules, and the head of the spleen was infiltrated with cancerous deposits. There was also cancer of the stomach, but there were no secondary deposits of the liver. The kidneys were apparently healthy. In the right pleural cavity there were about three pints of clear serous fluid. The right lung was compressed and was adherent at the upper portion of the chest wall. The bronchial tubes were thickened. The single symptom which led Dr. VanGieson to make the diagnosis of mesenteric cancer was the fact of oedema of one limb, without disease of the heart or kidneys. In a similar case, the specimens from which he presented to the Society seven or eight years ago, oedema was quite characteristic, whereas he believed in simple cancer of the stomach, oedema was very rare unless some other organs were involved, as the kidneys or the heart. There was no ascites.

DR. VAN SANTVOORD said that Trouseau had directed attention to oedema of one of the lower extremities as a symptom of malignant disease within the abdominal cavity, and regarded it as a valuable aid in making a diagnosis in case of obscure abdominal affections.

FIBRO-MYOMATA OF THE UTERUS OF THE SEA-LION.

DR. LIAUTARD presented the uterus and its appendages removed from a sea-lion belonging to Barnum's collection of animals. The animal had exhibited no special symptoms of disease, and had a good appetite up to twenty-four or thirty-six hours before death. At the autopsy there were found double pneumonia and parasites in the small intestine, and at the junction of the left horn with the body of the uterus there was found a large tumor which presented the gross appearances of fibromyoma as it occurs in the human subject.

CYST CONTAINING HAIR.

Dr. Liautard also presented a cyst containing hair which he had removed from the side of a saddle-horse, a little posterior to the left shoulder. At that point there was a movable elongated tumor, about the size of an English walnut. After making an incision through the skin the tumor was easily enucleated, and when opened it was found to contain a large amount of curly hair, mixed with sebaceous material. Another tumor, similar in feel, and about three inches in length, was removed from another part, and on opening it, it was found to contain material which presented the appearance of pus. He had been unable to find the record of any case of cyst containing hair occurring in the horse.

CARCINOMA OF THE RECTUM.

DR. JANEWAY presented a specimen with the following history: It was removed from the body of a man

twenty-eight years of age. Last June he suffered from dysentery, which continued up to the time of his death. Upon closer examination it was found that he had suffered from constipation for two years, and that from January to June, 1882, the constipation was such as to oblige him to strain severely before he could have a passage from the bowels. Nothing more definite could be obtained with reference to the character of the discharges than that they were rather small. When Dr. Janeway first saw the patient he was very much emaciated, his abdomen was swollen and contained fluid. There was also a certain amount of tympanites, and there was pain upon pressure. There was no doubt concerning the existence of chronic peritonitis. On making rectal examination he found, four inches from the anus, a stricture into which he could just introduce the end of his finger. The condition of the abdomen was such as to prevent a bimanual examination with one finger in the rectum. Near the umbilicus a tumor was found which was firm, hard, and situated in the deeper tissues. The skin was movable over it; it was of a flat, oval form, apparently about two inches in diameter and about one inch in thickness. The examination provoked a desire to have an evacuation from the bowels, and it was then seen that the size of the discharge was about that of an ordinary lead pencil. Dr. Janeway diagnosed malignant disease. The patient lived two years from the time of the first development of notable constipation, and died of heart failure.

At the autopsy there was found chronic peritonitis, and the peritoneum was also studded with nodular growths, which presented somewhat the appearance of miliary tubercle. There was new growth in the rectum, beginning about four inches above the anus and extending upward, so that the stricture measured four inches in length. The sigmoid flexure was likewise involved in the thickening and was also narrowed, so that the entire narrowed portion of the intestine, from the anus upward, was about six or seven inches in length. Another point of interest was a fistulous communication between the small intestine and the rectum. Another point of interest was that the cæcum and the ascending, the transverse, and the descending colon, were impacted with exceedingly hard masses of feces. Another point of interest was the fact that there was only slight ulceration of the mucous membrane of the intestines, the chief lesion being simple catarrh. There were one or two spots of ulceration in the rectum below the stricture. The mucous membrane was markedly thickened. The omentum was transformed into a cancerous mass, and could be felt as a tumor through the abdominal wall. The lungs were normal. There was no change in the pleura. One interesting and important clinical feature of the case was the fact that the patient came for treatment supposing that he was suffering from diarrhoea or dysentery. Dr. Janeway thought that every case of cancerous stricture of the rectum he had seen had given the history of treatment for chronic and sometimes for acute dysentery.

Another point of interest with reference to the specimen was the reaction given by the material of which the omental mass was composed. It had the glistening gross appearances of colloid material, but when acetic acid was used the reaction was that of mucous rather than of colloid substance.

DR. BRIDGON remarked that he had seen many cases of cancer of the rectum, but he had not seen one occurring in a patient under forty-five or fifty years of age.

DR. JANEWAY remarked that he had seen one case occurring in a man twenty-five years of age.

DR. BOZEMAN referred to a case at present under his care in which the patient was seventy years of age. The disease occupied the anterior wall of the rectum, about two inches above the anus. In that instance the patient had been told that she had, and had been treated for, hemorrhoids. Hemorrhoids existed, but the cancer was the essential disease.

DR. PEABODY then presented a specimen of

CHRONIC HYDROCEPHALUS, WITHOUT SYMPTOMS.

The brain was removed from the body of a man who died as the result of injuries caused by his being crushed between railroad cars. He was a vigorous man, about thirty years of age, in good health at the time of the accident. His pelvis was crushed and his urethra was lacerated. Following this came infiltration of urine. He died forty-eight hours after the accident.

The only organ of interest at the autopsy was the brain. After removal of the dura mater the convolutions presented a normal appearance. During the process of removing the brain from the skull there was an escape of fluid from the ventricles through the rent in the base which occurred just in front of the optic commissure. Immediately thereafter a large depression was found in the convolutions of each hemisphere, anterior to the fissure of Rolando. Upon opening the lateral ventricles the cause of this depression became apparent. Their cubic contents must have been fully as great as usual, their walls being much thinner than normal—nowhere more than an inch in thickness. The third ventricle was also dilated. The fourth ventricle appeared normal. The ependyma of the lateral ventricles was normal. The brain tissue itself was normal in consistency and color.

There was no abnormality in the shape or appearance of the skull.

The case was of interest in showing the extent to which chronic hydrocephalus could exist without symptoms which would lead to a suspicion of its presence. Unfortunately, of the man's mental capacity no history had been obtained.

DR. F. W. JACKSON referred to a case which came under his observation while an interne at the Roosevelt Hospital. A man, twenty-two years of age, gave the history of having been perfectly well up to eight years before admission, when he fell forty or fifty feet, as he stated, and struck upon his head. Beyond a certain amount of concussion he suffered but little from the fall, and remained as well as usual up to six months before seeking admission to the hospital, when he began to have attacks of severe headache, which increased in severity and frequency. On examination no apparent cause could be found for the headache. The attacks had become so frequent that they recurred nearly every half hour, and the pain was extremely severe. The man died suddenly. At the autopsy, made by Dr. Delafield, dilatation of the ventricles of the brain, nearly as marked as in the specimen presented by Dr. Peabody, was the only abnormal condition.

DR. GIBNEY had noticed spastic contractions in cases of chronic enlargement of the head, the majority of cases, however, in which such contractions occurred being in microcephalic children. He asked if the comparative frequency had been noted.

DR. JANEWAY remarked that his attention had not been especially directed to such cases associated with enlarged heads.

DR. VAN SANTVOORD said that a few years ago, while looking up the literature of spastic contractions, he read the history of a case of dilatation of the lateral ventricles in a man, forty years of age, which apparently dated from an injury received at twenty years of age. There was some feebleness of mind, and, besides, spastic paralysis without any lesion of the spinal cord. The writer referred to the spastic condition and the internal hydrocephalus as having the relation of cause and effect.

DR. JANEWAY thought it difficult to prove that the spastic condition depended upon the dilatation of the ventricles unless there existed descending degeneration of the lateral tract. He had seen quite a number of cases of chronic hydrocephalus in adults without any such lesion, nor was there spastic contraction. He also referred to the case of a boy with an exceedingly large head, and at the autopsy the thickness of brain substance

between the ventricles and the external surface was not more than one-eighth of an inch. There was also pachymeningitis of recent date with the hydrocephalus, but there had not been spastic contraction.

DR. BIRDSALL had seen a number of spastic cases, and scarcely any of the patients had heads larger than normal, while one or two were decidedly microcephalic. He had noticed the existence of spastic condition in children which were born at eight months, or less than full term.

The Society then went into executive session.

Correspondence.

OUR PARIS LETTER.

(From our Special Correspondent.)

THE EPIDEMIC OF TYPHOID FEVER IN PARIS, AND ITS LESSONS—THE CONTRACTILITY OF THE UTERUS UNDER ELECTRICAL CURRENTS—CHARCOT ON THE SITUATION OF OVARIAN PAIN AND THE ORIGIN OF HYSTERICAL ATTACKS—CREMATION IN FRANCE—DEATH OF CORVISART—PRESENTATION TO MONSIEUR DUMAS.

PARIS, December 29, 1882.

THE epidemic of typhoid fever which has been raging in Paris for some months past is, I am glad to say, steadily on the decline, and, if it has had no other result, it is worth noting that it has aroused the attention of the municipal and medical authorities to the sanitary condition of this great city, which is, in many respects, so notoriously defective and far behind that of many other cities of less importance. The etiology of the disease has been fully discussed at the Academy of Medicine and the different medical societies here, and, judging from the various opinions expressed, it is evident that the French medical men are becoming converted to the theory of the fecal origin of typhoid fever, though at the same time they do not lose sight of the other possible causes, such as foul air and water, overcrowding, and everything that would tend to debilitate the constitution. From the discussion on therapeutics it may be gathered that among medicinal agents quinine takes the lead, and it is considered by some almost as much a specific for the disease in question as it is for intermittent fever.

Other defects have come to light during the discussions, and the authorities are quite puzzled as to the carrying out of the sanitary measures proposed. The want of a more competent authority than the Municipal Council is also greatly felt—that is to say, a sort of State Board of Health, which, for some unaccountable reason, does not exist in Paris. This desideratum has been brought to the notice of superior authority, and it is hoped that ere long the "centre of civilization" will be endowed with a regularly organized body of medical men who will have proper control over all matters concerning the public health, instead of leaving them, as at present, in the hands of laymen.

At the last meeting of the Academy of Medicine, Dr. Onimus communicated the results of some experiments that he had made on the contractility of the uterus under the influence of electric currents, which may be summarized as follows: In the ordinary state it is difficult to determine uterine contractions by electric currents or by other excitants. In the gravid uterus, on the contrary, it is easier to do so; but even then it is necessary that, from whatever cause, physiological contractions must have already begun in it. This difference in the results produced is of the highest importance in a medico-legal point of view, as well as in their therapeutic applications.

Professor Charcot has been trying some experiments at the Salpêtrière Asylum in order to prove that ovarian pain in hysterical subjects is really situated in the ovary itself, and that the various phenomena, such as the arrest

of hysterical fits, the rousing of hypnotized subjects, etc., which are determined by pressure over the iliac regions, are really due to the ovary itself. In confirmation of his statement he read a paper before the Société de Biologie in which he gives the cases of two hysterical women who were in the family-way, and in whom the painful spots were rather higher than in women in the unimpregnated state. They rose according to the development of the uterus, and descended to their usual position after parturition.

Cremation does not seem to make much progress in France, notwithstanding the strenuous efforts made by some of its partisans in support of it. An attempt is being made to make it a matter for legislation by having the subject laid before Parliament, with the view of rendering this mode of sepulture legal. The proposition is to be submitted by M. Casimir Périer, and in the name of other distinguished men who are in favor of cremation.

Baron Corvisart, late physician to Napoleon III., died suddenly on December 26th, at his residence at the Champs Elysées, in Paris. He was the son of the celebrated Baron Corvisart, who was physician to Napoleon I. He had not done much in the way of practice, and lived quite retired since the fall of the Empire.

The Minister of Public Instruction has ordered a bust of the late Professor Bouillaud to be placed in the hall of the Institute.

The President of the Academy of Sciences has had the satisfaction of presenting to Monsieur J. B. Dumas a casket containing three medals—of gold, silver, and bronze, respectively—and each bearing an effigy of the illustrious chemist, to celebrate the fiftieth anniversary of his membership of the institute. Monsieur Dumas has been Permanent Secretary of the Academy of Sciences for several years.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE QUESTION OF LONDON DOCTORS SUPPLYING THEIR OWN MEDICINES—THE PROPRIETORSHIP OF PHYSICIANS' PRESCRIPTIONS.

LONDON, January 4, 1883.

THE question of doctors supplying their patients with medicine as well as with advice is a vexed one, and one about which there has lately been renewed discussion. In this country it is almost universally done—that is, by general practitioners. Consultants, of course—whether physicians, physician-accoucheurs, surgeons, or specialists—invariably write prescriptions, which their patients take to a druggist to have dispensed. The patient, therefore, first pays his doctor's fee, and then purchases his medicine at a druggist's. The general practitioner, on the other hand, usually runs bills, and when he makes out his account makes an inclusive charge for advice and medicine. Formerly—*i. e.*, thirty years ago—the custom was to charge for the medicine only, and not charge for advice. The usual thing now is to charge so much for each consultation or visit, varying the charge somewhat according to the position of the patient, and not make any charge for the medicine. The result is much the same in either case. A practitioner who refuses to supply medicine and writes prescriptions, soon finds that it does not pay. A patient consults his family doctor, say for bronchitis, and is charged from half-a-crown to seven shillings. If he receives a prescription, he takes it to a druggist's, who charges him, say, two shillings. In three or four days he wants another bottle, and pays a second visit and second fee—not to his doctor—but to his druggist. If the case is not serious the patient may continue his visits to the druggist until cured. The latter then may receive from a patient during a bronchitic attack fifteen shillings or a pound, three-fourths of which will be profit, while, the medical attendant may only receive his fee for a single consulta

tion. When the latter is only five shillings (and it is only in very good class general practice that more can be charged), it will readily be imagined that his practice will not prove very profitable. Some medical men send their prescriptions themselves to a druggist to be dispensed. They make their own arrangement with the druggist, paying him so much a bottle all round. Their patients pay them as in other cases, so the only difference between this and the ordinary method is that they are saved the trouble of doing their own dispensing, although in the eyes of their patients they still supply medicines. This plan has had to be abandoned by almost every medical man who has tried it, on account of the rates druggists usually charge them in such cases.

Another objection is, that the druggist may supply the medicine on his own account; and lastly, and this is perhaps the greatest objection of all, he may actually undertake to prescribe for the patient, and the medical man may thus lose his patient altogether. Where the patient receives a prescription and is free to go where he likes to get his medicine, these objections are still stronger. The patient will get it repeated time after time without further advice, and this kind of practice, on small fees, does not pay. A patient who pays his physician a guinea and receives a prescription, regards that prescription as his property. If he derives benefit from it he will continue to use it, and that, not only himself, but may copy it for, or lend it to his friends afflicted with a similar, or, it may be, dissimilar complaint. The consequences in some cases may be imagined. Unless seriously ill, or unusually fidgetty about himself, he will not pay his physician a second visit at all. Of course, a medical man who receives a guinea for every prescription is better off than a general practitioner, who attempts to do a prescribing practice, and charges only a fourth of that sum. Still it is a difficulty, and an increasing one, in consulting practice. Those who write prescriptions so as to be understood by one druggist alone, to whom they recommend, or rather send, all their patients, are tabooed by their medical brethren. In this case, it is, of course, understood between the doctor and the druggist that the latter is not to repeat without orders from the former, and rumor has it, that in some cases the medical man has actually condescended to receive a percentage of the druggist's profits. Still, even here, the druggist is master of the situation if he choose to be dishonest and break his agreement. The system of writing for one particular druggist alone cannot be commended. What is a desideratum, however, is that no druggist should repeat any medical man's prescription, either at his own or the patient's suggestion. The prescription should be retained by the druggist, and afterwards returned to the practitioner. Even here, the patient could not be prevented from copying it. Moreover, the public will not agree to it. A patient says: "I have paid Dr. So-and-so a guinea for this prescription, and it is mine—my property to employ as I please either on myself or on any one else."

The subject is certainly one on which improvement is possible. I do not see how much can be expected, however, when our leading journal takes the following position: "A medical man either dispenses or prescribes. If he prescribes, the prescription ought to be the property of the patient, *to be used when and how he pleases*, and ought to be written so that it may be compounded by any legally qualified chemist." The italics are my own.

ABSTRACTION OF BLOOD FROM RIGHT HEART.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I have been greatly interested in Dr. Westbrook's article "On Abstraction of Blood from the Right Heart as a Means of Relieving Intense Pulmonary Congestion," which appeared in your valuable journal of December 23, 1882. I regret the unfortunate termination of the

case upon which he operated, but believe, that so far as that particular case was concerned, the ordinary, time-honored method of performing vivisection, would have given greater promise of successful issue.

Dr. Westbrook deserves great credit for boldly demonstrating "that the right auricle may be readily aspirated, and that the introduction of a canula into its interior is not accompanied by alarming symptoms, or followed by unhappy results." The nearest approach to priority in this discovery, I believe to be in the somewhat vague reports concerning the temerity with which the Chinese practise acupuncture of thoracic and abdominal viscera; but I am not aware that they have deliberately marked out the boundaries of the right auricle with the avowed purpose of puncturing it. Now, I desire to use your instructive columns for the purpose of making a few suggestions, which are not inconsistent with the points established by Dr. Westbrook's operation, and which he may feel constrained to carry out. I want to ask him to abandon the idea of abstracting blood from the right heart for the purpose of relieving the intense pulmonary congestion incident to pneumonia, retain the important point that the introduction of a canula into the cavity of the heart is not attended by unhappy results, and use it in the treatment of valvular disease of the heart. I need not remind him that the famous "Dublin Committee," when studying the causes of the heart-sounds, thrust needles and hooks through the cardiac walls, and pushed aside and held back the several valves of the hearts of living dogs and sheep and bullocks. It would revolutionize the treatment of mitral regurgitation and aortic insufficiency. In a little while the average professor of surgery would divulge the insufficient aortic opening, and stitch up the delinquent mitral valves with the same audacity that he now cripples the urethra or closes a lacerated cervix.

HAL. C. WYMAN, M.D.

DETROIT, MICH., January 5, 1883.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I cannot refrain from asking through you one or two questions suggested by the article in your issue of December 23, 1882, entitled "On Abstraction of Blood from the Right Heart as a Means of Relieving Intense Pulmonary Congestion."

The writer describes a severe case of croupous pneumonia of the right upper lobe, which had lasted five days when he first saw the patient, a vigorous German. The next evening (of the sixth day) pulmonary oedema threatened, and to relieve the heart of a portion of its burden, aspiration of the right auricle was attempted—an operation, we are told, which had suggested itself to the author about a year previously. It met with poor success, but later in the evening the needle was re-introduced, and a little over three ounces of blood were withdrawn from the auricle. Relief seemed to follow, but the patient died suddenly next morning. At the autopsy, in addition to the pulmonary lesions, the courses of the two punctures into the heart were made out, and claret-colored serum and pink coagula were found in the pericardial sack. These were in part referred by the writer to leakage—hæmo-pericardium. Two facts are claimed as hereby established: first, that it is easy to needle the right auricle; second, that no unhappy results, immediate or remote, ensue.

I should like to ask how this latter conclusion can be justly drawn from the experiment. Was the hæmo-pericardium, however slight, not an "unhappy result?" And is there no risk in an operation involving such a contingency? Bearing in mind the tenuity of the auricular wall, and the danger that it shall tear itself by motion against the needle (not a fanciful danger by any means), can we consider its puncture other than a most hazardous expedient?

It has, I believe, been usually so regarded. With a

patient in the very act and article of death by pulmonary cedema, with no time to spare for phlebotomy, but when instant relief must be given to the very heart itself, it is conceivable that pneumatic aspiration of the right auricle may be justified; and I have known of its being resorted to in such an extremity. But in the case described, the patient was not *in articulo mortis*—he survived the second needling some twelve hours. If blood-letting, therefore, were indicated, there was plenty of time to take it from a vein in the ordinary way. What was here to be hoped from aspiration of the heart which could not be accomplished by bleeding from its feeders? Why bleed from the heart rather than from the arm? Was it easier, safer, more efficient?

WM. T. CHEESMAN, M.D.

AUBURN, N. Y.

THE CARE OF THE CHRONIC INSANE.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: An article appeared in THE MEDICAL RECORD of December 23d inst., on "The Care of the Chronic Insane," which I would not have felt called upon to notice, except in commendation of its general objects, if the writer had not gone so far as to make statements calculated to arouse distrust, ill-founded and unwarranted apprehensions, in regard to existing institutions of the State. When it was proposed, for good and sufficient reasons, to create an asylum for the chronic insane in this State, fifteen years ago, it was quite the fashion to make predictions similar to those contained in this article. It is true that at that time there had been no experience on which to base any intelligent opinion, but since the results, direct and indirect, of the operation of the Willard Asylum have been before the public, it may be a fair question whether Dr. Agnew is justified in taking counsel wholly from his apprehensions or the fears of others. Certainly, no one of the prophets of evil consequences to result from the establishment of this asylum, or any of the watchers, have so far felt called upon to remind the public or the profession of his prescience. Dr. Agnew may be assured his fears are groundless, so long as the public asylums of the State are surrounded by proper safeguards. Neither do I agree with the statement that it has been demonstrated that it is "unscientific," "inhumane," or "bad as it can be in an economic point of view" (strong expressions), to place the acute insane in one institution, and the chronic in another. If any result has been clearly demonstrated in this State, it has been quite the other way.

The article seems to have been suggested by resolutions of the Supervisors of Dutchess County, "pointing out the necessity of caring for the chronic insane nearer their homes," and urging the necessity of creating a department for them in connection with the Hudson River Hospital at Poughkeepsie. It is, however, suggested that one thousand to one thousand five hundred patients be transferred from the New York Asylums to the Hudson River Hospital, which would be practically a removal from the vicinity of their homes, and a conversion of one or the other asylum into a chronic asylum, which Dr. Agnew sees no objection to in this particular case.

One word upon the general question of the care of the chronic insane. Those of your readers who recall the history of lunacy legislation in this State (and others should be reminded of the fact), will remember that it was the original design of the managers of the Hudson River Hospital, publicly announced, that it should be a *hospital* for the treatment of recent cases, and not an *asylum* for the chronic insane. It was adherence to this policy, and the exclusion of the chronic class by this and other hospitals, and their return to county poor-houses, that led to the creation and enlargement from time to time of the Willard Asylum, in order that some system of care might be provided other than that shown by official reports to exist in those receptacles.

About the time the Hudson River Hospital (of which Dr. Agnew was then, as now, a manager) was ready to receive patients, application was made by the Superintendent of the poor of Dutchess County for the admission of certain patients into the Willard Asylum. He was, in reply, requested to apply for the reception of these cases into the Hudson River Hospital, as they were almost beneath its shadow. A second letter of application was received, to state that the coming winter and insufficient heating apparatus in the County House would expose these persons to suffering, and that, having applied at the Hudson River Hospital, admission was denied on the ground that the hospital was intended for recent cases. Among the transfers made from that county was the case of a man who had worn shackles and a chain attached to the floor for a period of fifteen years.

The following case illustrates another phase of this question: On December 20th, inst., a man was admitted into the Willard Asylum, who had been a patient in the Hudson River Hospital, and afterwards removed to a county poor-house, perhaps, for the reason that he could be maintained there cheaper than at the hospital. In the County House this man wore iron handcuffs, shackles of iron about his legs, and a chain connecting the shackles with the floor. All this, too, in the State of New York!

The experience of these two counties in which proceedings were taken as prescribed by law, presents the practical suggestions: first, that the work of caring for the insane must not proceed on a scheme which is purely "scientific;" and, second, when plans of construction are devised that will not be too expensive to execute; not involve too much expense to administer when completed; and a standard of care and maintenance adopted more in accordance with the reasonable views of the taxpaying portion of the community, it is quite safe to predict every incomplete asylum in the State will be speedily finished, and county care of the insane abandoned, but not before.

Respectfully yours,

JOHN B. CHAPIN.

WILLARD, N. Y., December 30, 1882.

THE QUESTION OF RETROSTALSIS AND THE ABSORPTION OF ENEMATA.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I enclose a few notes upon a peculiar case of seeming retrostalsis, after rectal injections, which came under my observation in the medical ward of St. Luke's Hospital last winter. It seemed to be of interest in connection with Dr. C. L. Dana's paper upon that subject in THE MEDICAL RECORD of January 6th.

The case, briefly stated, was as follows: Sarah B., aged twenty-three, single, house-work, admitted February 6, 1882. Dr. Wm. C. Campbell, house physician. Besides a slight pleuritis, she was suffering from well-marked symptoms of peri-uterine cellulitis, going on to the formation of abscess, which opened into the rectum March 1st. By March 6th the purulent discharge had ceased, and examination showed the uterus and vagina to be still held firmly bound by inflammatory material, but no localized collections of pus. No opening into the rectum could be discovered. Bowels became very constipated, and the previous flatulence and vomiting became more severe. Nothing could be retained upon the stomach. After consultation with several members of the visiting staff of the hospital, it was deemed advisable to open the bowels thoroughly; so, on March 13th, at 10 A.M., a stimulating enema was given (ol. ricini, ʒj.; spt. terebinth., ʒss.; ol. olivæ, ʒij.; aquæ, Oj.). No result. Two hours later another enema was given, with an increased amount of turpentine and castor-oil. Result, a free movement, followed in a short time by vomiting and symptoms of a collapse. The vomiting soon became stercoraceous, and the vomited material smelt strongly of turpentine, and

was somewhat of the consistency of paint. Upon the surface free oil was floating. In about two hours this disappeared, and collapse gradually became more profound. March 14th, 3 30 P.M., patient died.

At the autopsy the large intestine was distended with fœces, and at the lower border of the transverse colon, near the hepatic flexure, a perforation had taken place with extravasation into the peritoneal cavity. Stomach normal in appearance and empty.

HENRY MOFFAT, M.D.,
House Physician, St. Luke's Hospital.

NEW YORK CITY, January 7, 1883.

Army News.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from January 6, 1883, to January 13, 1883.

SKINNER, JOHN O., Captain and Assistant-Surgeon. Granted leave of absence for one month. S. O. 5, par. 2, A. G. O., January 6, 1883.

WOOD, MARSHALL W., Captain and Assistant Surgeon. Granted leave of absence for one month. S. O. 4, par. 3, Department of the East, January 8, 1883.

JOHNSON, R. W., First Lieutenant and Assistant-Surgeon. Granted leave of absence for one month. S. O. 4, par. 2, Department of Dakota, January 5, 1883.

MUNDAY, BENJAMIN, First Lieutenant and Assistant-Surgeon. Assigned to duty at Fort Klamath, Oregon. S. O. 195, par. 3, Department of the Columbia, December 29, 1882.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Comparative statement of cases of contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending January 13, 1883:

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
January 6, 1883	0	6	64	10	46	52	0	0
January 13, 1883	5	9	75	1	64	54	0	0

THE NEW YORK MEDICO-LEGAL SOCIETY.—In his inaugural address, recently delivered, Mr. Clark Bell said that the society's membership had increased during the past year from 177 to 267: that 367 volumes and 564 pamphlets had been added to the library, and that four members, Drs. J. R. Wood and Hagan, ex-Minister E. M. Stoughton, and Assistant United States District Attorney Herrick, had died during the year. He recommended that legislation be secured through the action of the society to amend the lunacy laws and the law relative to coroners, to decide who are experts and what is proper expert testimony, and looking toward improving the sanitary condition of school buildings. He also advised the publication of a medico-legal quarterly under the auspices of the society, and the establishment of the office of a State Chemist, at a salary not to exceed \$10,000 a year, and the establishment of a State chemical laboratory under his charge, where all analyses needed in criminal cases shall be made for either the State or the defence.

SUICIDE OF A MEDICAL STUDENT.—A young medical student, Mr. Norman W. Smith, who was studying at the Medical College in Atlanta, Ga., committed suicide on January 7th. He was a young man of excellent character and habits, and was in apparent good health at the time. He left no explanation of the act; but the scrupulous care and unusual attention to all the possible post-mortem contingencies betrayed a morbid mind, however.

CONSUMPTION OF TOBACCO.—According to *Les Mondes*, it appears that in Russia, France, and England, the consumption amounts to 1 lb. per inhabitant. In Italy it is rather higher, 1½ lb. Austria comes next with 2-2½ lbs. In the United States and Germany the consumption amounts to 3 lbs., in Belgium to 4-4½ lbs., while Holland has the privilege of heading the list with a consumption per inhabitant of more than 5½ lbs.

CARDIAC NEURASTHENIA.—In some cases of exhaustion from continuous overwork, the symptoms centre chiefly about the heart. The symptoms are feeble cardiac action, giddiness, weakness, intermittent beat. Palpitations, dyspnoea, and even syncope, may be present. A physician who suffered in this way for some time writes to the *British Medical Journal* that he was relieved entirely by the following prescription: R. Quinin. sulph., gr. xxiv.; mist. camph., ad ʒvj.; acid. hydrobromic. dil., ʒiij.; tinct. digital., ʒss.; liq. aurant., ʒj.; tinct. nuc. vom., ʒij. M. Sig., ʒss. three times a day.

RECTAL EXAMINATION IN VESICAL CALCULUS.—The *Edinburgh Medical Journal* calls attention to R. Volkmann's article in *Centrab. für Chirurg.* In children suffering from vesical calculus a bimanual method of examination through the rectum and above the symphysis is of great value. Anæsthesia is necessary, and the abdominal walls should be thoroughly relaxed. The fingers of the left hand in the rectum raise the stone, the bladder being empty, and the right hand guides it to the symphysis pubis. If the stone is not too large, it may be so far raised that a string could actually be passed around it. In adults the operation of course would not be so successful. —*Chicago Medical Review.*

THE NEW YORK SKIN AND CANCER HOSPITAL.—An hospital under the above name was incorporated in this city last month. Among the trustees are Dr. James Knight, Dr. C. R. Agnew, Edward Winslow, G. H. Scribner, and others. The hospital physician is Dr. Bulkley, and Drs. Robert F. Weir and Edward L. Keyes are operating surgeons. In a circular asking for money the trustees say that they do not ask merely enough for the current expenses of their present small building, but they desire to purchase immediately real estate, already selected, upon which to erect a structure suitable for the purpose for which the hospital was incorporated. An idea of the proposed building is given in the statement that "a capacity equal to that of the New York or Roosevelt Hospital could be utilized at once."

THE RESULTS OF IMPROVING THE MILK.—As a result of the improved quality of milk now brought to this city, the mortality among children under five years of age has decreased from 52 per 1,000 to 46 per 1,000.

SEVERE POISONING BY BELLADONNA PLASTER—RELIEF BY MORPHINE.—Dr. W. H. Mather, of Suffield, Conn., sends us the history of a very interesting and somewhat unique case. Last March Mrs. W. had a severe attack of bronchitis with much coughing and expectoration. One of the remedies used was a belladonna plaster about seven by seven, which was placed over the left lung. It remained on for six weeks, when it began to annoy her, and she occasionally raised part of it and rubbed the surface of the skin beneath. Dr. Mather writes: "I removed the plaster entire one evening and rubbed the surface freely with my dry hand. The plaster was then replaced. On the morning following my patient could not see clearly. At 9 A.M., she went to bed and ordered the

servant to look in upon her now and then lest she might not be in her right mind when she should awake (she never went to bed in the forenoon before). After one hour she awoke in a terrible dread—suffered a sense of suffocation—of impending danger—of imminent death. Sensation was nearly gone from the extremities; the throat was dry, the pupils dilated, the pulse could not be found. The heart had almost stopped, and was feeble beyond experience. Had it not been for whiskey, vigorously applied externally with friction, and internally she would probably have died before help could be had. She felt impending suffocation, as if she were fighting for dear life every breath she could get. This fear and prostration lasted four hours. Then quiet continued until forty-eight hours after, when, on making exertion to dress and walk down stairs, the same symptoms recurred. Three physicians attended her during the half-day. One believed that morphine would be fatal. I said I would risk it. No sooner had the morphine been absorbed than a calm quiet supervened. The feelings of dread, fear, and terror were banished. The whole system was severely shaken for two weeks. Digestion was impaired and constipation was complete; the mind was weak. She complained constantly of being 'so tired, so tired.' Large quantities of urine were passed during the stage of greatest prostration." The patient had been asking for glasses for a week, but the plaster was not thought of. Dr. Mather thinks that he broke off many little papules when the skin was rubbed.

DR. ROSEBRUGH'S NEW MEDICAL BATTERY.—Dr. Almon Clark, of Sheboygan, Wis., sends us a letter criticizing Dr. Rosebrugh's new medical battery, as described on page 641, MEDICAL RECORD of December 2, 1882. He claims,

First.—That by using bearings attached to the cover of the battery case, instead of the spring posts and clamping nuts, Dr. Rosebrugh only adapts a plan carried out in Dr. McIntosh's cheap domestic machine, but not in his larger batteries, because for the latter it is an inefficient arrangement.

Second.—That Dr. Rosebrugh's method of immersing the elements is of such little advantage that it does not counterbalance the inconvenience of the increased length of the box.

Third.—That when Dr. Rosebrugh says: "Some batteries are provided with an extra acid-cell and an extra pair of elements for the faradic coil, the extra cell being placed to the right of the coil. When this is the case, a space for the overlapping of the hydrostat plate is afforded by simply uncovering this extra acid-cell," he simply suggests a new method of using the battery, but does not, according to Dr. Clark, the writer of the letter, improve the said battery.

SUICIDE IN DENVER, COLORADO.—At a meeting of the Denver Medical Association on December 12, 1882, Dr. Steele read a paper on the "Prevention of Suicide." Seventeen cases had occurred in Denver alone during the past year, which makes an enormous ratio. A committee on Medical Legislation was appointed, to whom the paper was reported. The object is, if possible, to secure certain medical legislation in regard to the sale of poisons by druggists; to punish those who attempt suicide and fail, also those who in any way aid or assist those contemplating self-destruction.

ANointing WITH OIL.—There are several well-established faith-cures in this city, and they are doing, we are told, very effective work. To the list is now added the anointing with oil process introduced by the Mountain Evangelist Barnes, who is now preaching here. This gentleman, after the anointing ceremony, lets a little light upon the *rationale* of his success by laying the following injunction upon his patients. He says: "Distrust symptoms, they are tests of your faith. Whether you feel better or worse, say 'I am healed by faith,' and it will be so."

GRAND RIVER MEDICAL ETHICS.—At a meeting of the Grand River Medical Society, December 5th, charges were preferred against Dr. Hanna, for consulting with an irregular practitioner. The charges were found to be sustained. On motion, Dr. Hanna was enjoined not to repeat the offence. Dr. Hanna acknowledged his error, thanked the Society for letting him off so easily, and said he would not do it again.

POLICLINIC OR POLYCLINIC.—Dr. John A. Wyeth writes: On page 28 of THE RECORD for January 6, 1883, occurs the following:

"*Policlinic* or *Polyclinic*.—The word *policlinic* is derived from *πολις*, a town, and *κλινη*, a bed. It means therefore and always has, since its introduction as a word, a city clinic or hospital. A frequent mode of spelling the word in American medical literature is *polyclinic*. This assumes arbitrarily, and incorrectly, that the word is composed of *πολυς*, many, and *κλινη*."

Your assertion that the word "*policlinic*" means a city clinic, no one will contradict, but the other assertion that it is "arbitrary and incorrect" to assume that the word *polyclinic* may be a compound of *πολυς*, many, and *κλινη*, is not correct.

When the New York Polyclinic was being organized, the construction of this word was discussed carefully and at length by the faculty. The conclusion arrived at was that the name of the "School of Practical Medicine and Surgery" should convey the idea that its plan of study consisted of *many clinics*. As for the construction of the word there are many precedents. For instance, the noun *polypharmacy*, from *πολυς*, many, *φάρμακον*, medicine; or the adjective *polyphonic*, from *πολυς*, many, and *φωνη*, sound, *χολυφωνος*, "consisting of many sounds." I hold that it is just as correct to name a school of medicine the *polyclinic* school, as to name a dictionary a *polyglot* lexicon.

[We publish Dr. Wyeth's letter with pleasure, but find nothing in it that would lead us to modify our first opinion, which is simply this: The word "*policlinic*," derived as we stated, is a part of the medical language of Germany, France, England, and America. Its etymology is authoritatively given in Dunglison's Dictionary as we gave it.

Our correspondent, like all free-born citizens, has the inalienable right of coining a new word if he chooses, but we believe it will be admitted that it is arbitrary and incorrect, as regards taste at least, to take a word whose spelling and usage have been established, and, by changing a single letter, make a new thing out of it. It leads to confusion, and the necessity of the change is not apparent. The Vienna Poliklinik has always gotten along well enough with the old-fashioned word.—ED.]

INEBRIETY AND DR. CROTHERS.—Dr. J. B. Stair, of Spring Green, Wis., writes: "A few weeks ago I had the honor to publish in this journal a short article in opposition to an idea of which Dr. Crothers, of Hartford, seems to be the chief exponent, in regard to the causation of inebriety. In the last number of THE RECORD I see a note from the doctor, presumably in answer to what I had written. It is scarcely necessary to say that it is a direct evasion of the points suggested in my letter; in fact, the doctor says the 'doubts' I raise 'cannot be answered by argument,' but that it is simply a question of fact, daily demonstrable, clinically. Dr. Crothers has probably spent as much time as any other man in trying to show, by argument, that his view of the question is the correct one; but when arguments are offered upon the other side of the question, he suddenly finds that it is not a debatable subject, nor a matter of opinion, but one of fact. His opponents will doubtless claim that their position, as a matter of fact, is the right one, but think it is a fit subject for discussion. Dr. C. should not forget that his theory is an innovation, and though it be a fact, it will have to stand the test of thorough discussion and sharp criticism before finding a place in the favor of the

profession. I am not a caviller, neither do I seek to call in question theories simply because they are new, but I can but regard the objections which I urged in opposition to Dr. Crothers's position as pertinent ones, and humbly submit that they, with many others, must be refuted—or must stand. The points raised in my letter are no more matters of opinion than are those urged by Dr. Crothers, and if facts alone are to be considered, we must be permitted to examine *all* the facts, *pro* and *con*. There are some questions which, in their nature, cannot be entirely taken out of the field of moral discussion. This is one of them."

SIR JAMES PAGET, in proposing the toast, "Prosperity of the British Medical Association," at the recent jubilee, uttered the following beautiful sentiment: "Do not let our disputes be very noisy on the scientific side. Remember always that it is only through clear and undisturbed water that you can see what lies at the bottom. In storms of controversy there is nothing to be found but the billow that moves to mischief and the foam that disappears."

AN APPEAL FOR THE VENTILATION OF CHURCHES.—Our contemporary, *The Christian Weekly*, publishes a very effective, though not strictly grammatical or scientific, appeal to the sexton for a better ventilation of the churches. We quote some of the lines:

"O Sexton!
You shet see men women and children
Speshly the latter, up in a tite place,
Sum has bad brethrs, none of em aint too sweet,
Sum is fevery, sum is scrofuls, sum has bad teeth
And sum haint none, and sum aint over clean;
But evry one of em brethes in and out and out and in
Say 50 times a minnet, or 1 million and a half breths an hour;
Now how long will a cherk full of are last at that rate?
I ask you? say fifteen minnets, and then what's to be did?"

"I put it to your konshens,
Are is the same to us as milk to babies,
Or water is to fish, or pendlums to cloz,
Or roots and airis unto an Injun doctor,
Or little pills unto an onepath,
Or Boize to gurls. Are is for us to brethe.
What signifies who preaches of I cant brethe?
Whats Pol? What Pollus to sinners who are ded?
Ded for want of breth?"

PHARMACEUTICAL CHEMISTS.—A wealthy New York importer of drugs characterizes the pharmaceutical chemists of Europe and America as follows: "The German chemists are the most thorough in the world, but they always deal in an inferior original article, their meanness being equal to their science. America excels in her experimentalism. The French administer nothing but simples, especially affecting ptisans."

THE PAY OF SHIP SURGEONS.—The pay of the medical officer on the steamship lines between England and America is grossly inadequate to the service and responsibility of the position. It is said that, on the line which carries more passengers than any other, he is paid less than the chief steward, and the same as the steerage steward and the *fifth* engineer. In this connection it is interesting to note that the proportion of deaths to those embarked by each steamship line in 1881 was:

On the Barrow Line	1	died in every 509 embarked.
" Monarch Line	1	" 751 "
" American Line ¹	1	" 867 "
" Anchor Line	1	" 1,346 "
" Guion Line	1	" 1,362 "
" Dominion Line	1	" 1,435 "
" State Line	1	" 1,461 "
" National Line	1	" 1,659 "
" Allan Line	1	" 2,575 "
" White Star Line	1	" 2,754 "
" Cunard Line	1	" 2,990 "
" Inman Line	1	" 3,313 "

Not included in this rate are the deaths of ten infants born during the voyage, and of fourteen members of the crews, besides seventeen others, composed of passengers and crew, who were drowned or committed suicide.

¹ British ships.

KOLA NUTS AND INEBRIETY.—The temporary popularity of coca as a remedy for the opium habit, seems likely to find a parallel in the use of the kola nut for inebriety. Some enterprising temperance people of London have imported a large amount of these nuts from Africa, and are proposing to use them in the cause of temperance. The kola nut (*sterculia acuminata*) contains a considerable amount of a volatile oil, and about two or three per cent. of *thein*. It is therefore allied in properties to coffee, tea, guarana and coca. It is much used by the natives of Africa for its agreeable stimulating effects.

THE GERMAN MEDICAL MIND.—Dr. J. F. Jenkins, of Tecumseh, Mich., writes: "Dr. Beard stated at a recent meeting of the American Academy of Medicine that 'the German physicians are the best educated physicians in the world, both in general and special training.' He also stated that 'the Germans are non-therapeutists.' The assertion that a class of physicians are the best in the world, notwithstanding they are non-therapeutists, is not the prevailing opinion relative to the qualities that make an educated physician. It is difficult to conceive how a man can be a first-class physician and a non-therapeutist, unless he is a homœopathist. Dr. Beard claims for Germany that nothing counts but originality. If he means the crude hypotheses that are found so thickly scattered through the volumes of 'Ziemssen's Cyclopædia' to pass for original thought, then we must confess that Germany is the country *par excellence*. 'This work has been sold by thousands in this country, while only a few hundred have been sold in England.' This statement does not by any means prove that the English physician is not up to the times, for very few busy practitioners have leisure to wade through these seventeen volumes for what little original thought he will find to benefit his patients. The following quotation is, we think, not quite correct; 'Outside of a small circle of German-taught experts, the medical literature and the medical practice of England is from five to fifteen years behind Germany and America.'

"If the above is a fair statement of facts, it would be difficult to account for the large percentage of English medical works that are used in our colleges. If I mistake not, the busy physician of the day, when surrounded by difficulties in diagnosis and therapeutical indications, almost invariably consults his American and English authors. The learned specialist may find in German pathology and medical philosophy (where no two of them agree) 'original thought' that the common medical mind cannot grasp."

THE SILICA SPINAL JACKET is recommended by Dr. George R. Fowler (*Annals of Anatomy and Surgery*) as a substitute for the plaster-of-Paris. It is applied just as silica bandages usually are, but over this jacket temporary plaster-of-Paris bandages are wound and left on for four or five days until the silica is dry. The silica jacket is light and strong. It is cut open in front and then laced. Dr. Fowler does not find it necessary to suspend the patients entirely, but lets the toes touch on the floor.

THE DANGER OF THE OLEANDER.—Dr. J. A. Wesinger calls attention (*Detroit Clinic*) to the poisonous properties of the Nerium Oleander, a plant so much cultivated in this country for ornamental purposes. Contact of the face with the leaves or chewing the leaves may cause fever, anorexia, and an eruption with papules and blebs which are very irritating.

The poisonous principle of the oleander exists in the leaves, bark, and flowers, but most largely in the bark. This principle is of a resinous nature, and not volatile, and is found more largely in the wild than in the cultivated plant.

THE TREATMENT OF ACUTE RHEUMATISM— THE COMPLICATIONS.

By ROBERTS BARTHOLOW, M.D., LL.D.,

PROFESSOR OF MATERIA MEDICA AND GENERAL THERAPEUTICS IN THE JEFFERSON
MEDICAL COLLEGE OF PHILADELPHIA, ETC.

NOTWITHSTANDING the apparent severity of acute rheumatism, because of the pain, and the extent of the joint mischief, the mortality—as all the world knows—is very small. The circumstances inducing a fatal result are immediate and remote; complications which are at once incompatible with life form one group; those inducing changes, which ultimately prove fatal, constitute the other group. Excluding the latter, which cannot be numerically estimated, the proportion of cases fatal to the whole number is about three per cent. The remote causes of mortality are, nevertheless, the more important.

In considering the treatment of the complications it is, of course, understood that reference is had to those arising during the acute symptoms; for example, the condition of hyperpyrexia, endo- and exo-carditis, myocarditis, embolism, embolic pneumonia, cerebral embolism, etc. I purpose, then, to consider these in turn, from the therapeutical standpoint; but as no proper therapeutical diagnosis is possible without a true conception of the pathological state, it is necessary to express my view of this state in order to establish a groundwork on which the therapy may be properly projected.

Irritation of a hypothetical heat-centre is surely too entirely theoretical to justify us regarding it as an adequate explanation of the *hyperpyrexia* of some rare cases of acute rheumatism. The extraordinary rise of temperature, the circulatory disturbances, and the cerebral oppression rather signify the onset of some inflammatory complication, as meningitis or pneumonia. That they may not be recognized, is true enough, but that they exist is equally certain. The therapeutical problem is how to diminish the extraordinary body-heat, rising, as it does in extreme cases, to 108°, 109° Fahr., even higher. Until the influence of excessive heat in the production of "parenchymatous degeneration" had been recognized, these cases of hyperpyrexia were looked upon as hopeless. Now, it is known that the timely use of antipyretics may obviate the tendency to death. The chief antipyretic is the cold bath, and next quinine and digitalis. The mode of employing these, their limitation and effects, are now so well known that it is not necessary to enter into details on these points. The bath cools the superficial layer of blood, quinine and digitalis depress the temperature—the result being the lessening of the body-heat sufficiently to prevent the disastrous parenchymatous degenerations. At the same time the inflammatory complications—the meningitis, the pneumonia, etc.—are improved. These therapeutical results are due, not to an action on a supposititious heat-centre, but to the impression made on the course of the complicating malady.

Much more frequent, and therefore more important from the point of view of practical therapeutics, are the cardiac complications, the endo- and exo-carditis—endocarditis and pericarditis. The relative proportion of cardiac complications cannot be exactly stated; but here we are

concerned with the management of these complications. Our object is to determine the plan of treatment which will yield the best results. We must, therefore, seek to obviate the ill effects of a condition in which the blood is changed in its constitution; in which the pericardium and the endocardium are thickened and roughened, and in which the propelling power of the heart is impaired. Good results are attributed to various plans of treatment, because of the disappearance of a murmur, almost constantly present during the maximum of any case of rheumatism. This murmur may be of little consequence. The damaged membrane and valves, and the excess of fibrin and leucocytes in the blood, are the important points, and the questions for the therapist to consider are, how change the constitution of the blood, how modify the morbid process going on in the inflamed membrane, and how prevent the damage in distant parts, whether it be exo- or endo-cardial inflammation, with which we have to deal.

In endocardial inflammation it is most necessary to render the blood as alkaline with ammonia as can be effected. The potash salts are too depressing to the heart to be employed for this purpose, and ammonia is a necessary constituent of the blood, serving in part to maintain its fluidity. The more promptly the ammonia is introduced, the less the damage to the valves, and the less the danger of embolisms. In pericarditis the same plan is useful in a somewhat less degree. In both endo- and exo-cardial inflammation the muscular structure is involved to some extent, and the power of the heart weakened, hence remedies such as digitalis which raise the peripheral tension of the vascular system, are not desirable, may be, indeed, dangerous. *Veratrum viride*, on the other hand, by lessening the amount of work required of the heart, serves a useful end; but, it seems to me clear, that aconite, judiciously used, is, on the whole, the most effective remedy for the inflammatory process. Quinine, in antipyretic doses, with morphia, if rightly timed, may do great good at the initiation of the endo- or exo-cardial inflammation, but the period passed, small doses only are indicated to sustain the waning power of the heart. Coincidentally with the administration of these remedies, a succession of small blisters, at or about the præcordia, will do good. The proper way to conduct the blistering is to apply a blister about two inches square; allow it to *vesicate slightly*, and then put another on in the neighborhood; thus a succession can be kept up, and a continuous influence maintained. The curative effect consists in the irritation of the cutaneous nerves, and not in the withdrawal of serum. The influence of blisters in causing an alkaline state of the urine has been mentioned; but this is only a part of the effect produced: the trophic centres are stimulated or depressed according to the extent or persistence of the vesication—stimulated by mild and transient irritation, depressed by deep and protracted irritation. Meanwhile a proper alimentation and the sustained support which a suitable food supply only can accomplish are most necessary to the successful issue of the case.

Endo- and exo-carditis are to be considered not only in respect to their immediate, but also to their ulterior effects. It would lead me far from my present purpose to consider these ulterior effects; but it would be taking a very narrow view of the pathogenetic relations of the subject to exclude the immediate results. I have merely

referred to the myocarditis, whereby the muscular substance of the heart is damaged, so that its propulsive power is diminished. When endocarditis coexists with pericarditis, inflammation extends by contiguity of tissue to the muscular substance, it undergoes granular degeneration to a less or greater extent, and its contractile elements are consequently weakened. Hence it is in some—fortunately, rather infrequent—cases that the work of the heart is done very imperfectly; the action is rapid but wanting in power. Under these circumstances some alcoholic food is highly useful—wines of good body and rich in ethers, old brandy or whiskey—and those muscular stimulants which increase at the same time the power and the nutritive energies of muscular tissue—especially *nux vomica* or its alkaloid, strychnine, the tincture of iron, quinine, and in some instances atropine.

When the valves of the heart are fringed with fibrinous vegetations, embolism of various organs must result. It is now perfectly well known that an embolus detached from the left valves, will usually lodge in the left middle cerebral artery, or some of its branches; and from the right valves, in some part of the parenchyma of the lungs. This accident will be the less likely to occur, if the treatment above indicated is faithfully carried out. Nevertheless, during the course of the cardiac complications of acute rheumatism, hemiplegia, with aphasia, embolic pneumonia, or embolic obstruction of some peripheral vessel may occur as a complication. The treatment of such a complication consists first, in efforts to restore the continuity of the obstructed vessel, and second, to obviate the local, vascular disturbances and consequent nutritional disorders. The only measure which promises even an approximation to success consists in the use of solvents of the fibrinous plugs or emboli, of which ammonia must be regarded as the chief. I know of no clinical experience in support of the practice of the intravenous injection of ammonia for the solution of fibrinous emboli, but as this method has been repeatedly resorted to with entire safety under other circumstances, it is in a high degree probable that it would be very beneficial in this case. One part of *aqua ammonia*, diluted with two parts of water, is an ammoniacal solution which has been injected into the blood repeatedly without any ill effects of any kind. If the intravenous injection may not be desirable, the usual means for securing the admission of ammonia to the blood—by the stomach—may be resorted to. Although the point of contact is minute, the impact of the alkalized blood may gradually bring about the solution of the embolus. In considering the treatment of the embolic processes, besides the obstruction at the point of lodgment of the embolus, our attention must be directed to the results. So much depends on the position of the embolus, as respects the office of the "terminal arteries," that no adequate conception of embolic obstruction of vessels can be had, which does not include in its purview the conditions known as "collateral hyperæmia and œdema." When, therefore, in consequence of endocarditis, embolic obstruction occurs, it is very important from the prognostic point of view, to know whether or not a "terminal artery" has been blocked. If a terminal artery, it is certain that the considerable area of devastation produced by the collateral changes must be added to those due to the mere obstruction. When, therefore, in the course of acute rheumatism with endocarditis, right hemiplegia with aphasia occurs, we may have to deal with a transient impairment of motility, or a more lasting hemiplegia, with accompanying disorders of motility, sensibility and speech. In the former we have a right to assume that the obstruction has occurred in an artery having numerous anastomoses, some of which have assumed the duty of supplying the obstructed area with its proper complement of blood. In the latter, we must conclude that the obstructed vessel is a terminal artery, and that to the localized anemia thus induced is super-

added the phenomena of collateral hyperæmia and œdema. In the former the powers of nature may be adequate to the restoration of function; in the latter, art must interpose. Any remedy administered in the former condition, at the right time, may seem to have accomplished marvels.

In cases of cerebral embolism the chief point is to prevent the mischief produced by the collateral hyperæmia and œdema. The best results are obtained from a combination of quinine, ergot, and digitalis, for the collateral mischief, and ammonia to effect the solution of the obstructing plug. The latter should be used in accordance with the principles already laid down, and the former should be kept up until some evidence of a satisfactory change in the local hyperæmia and œdema is manifest. It need hardly be observed that the caustic alkali, ammonia, should not be given at the same time with the ergot and digitalis. These principles are equally applicable to the treatment of embolic pneumonia.

In cases of acute rheumatism, complicated with endocarditis, one of the modes of dying is by embolic pneumonia. In this condition we have an adequate explanation of the hyperpyrexia in some cases. The peculiar shape and appearance of the inflamed area, are not without importance from the therapeutical standpoint, for here, it is obvious, there are conditions present which clearly separate embolic from the form of pneumonia called fibrinous or croupous. The latter, indeed, seems to be a specific disease—a self-limited malady—whilst the former belongs to the general class of inflammatory reactions due to non-specific, non-infective emboli. Embolic pneumonia should therefore be managed with strict reference to the nature of the local morbid process. Ergot, quinine, digitalis, morphia, are the remedies to check or prevent the change in the circulation of the part affected so long as such an action is possible; afterward, to favor the retrograde changes, attention must be given to the support of the natural powers.

During the course of the various secondary changes due to endo- and exo-carditis, an important element is the condition of the heart-muscle. I have already referred to this as a part of the morbid affection of the organ which must be considered in dealing with endocarditis and pericarditis. This condition has, however, wider applications. Myocarditis enters into the question of treatment, as of prognosis, in all the complications of acute rheumatism secondary to endocarditis and pericarditis, but, besides, in embolic pneumonia, the element of obstruction in the pulmonary circuit must be regarded.

CASE OF SUBPERICRANIAL CEPHALHÆMATOMA.—Dr. M. H. Battershall, of Attleboro, Mass., sends us the history of a case of the above nature. Dr. B. attended a primipara in labor, the pains having begun about two hours previously. Examination showed a slightly contracted pelvis, os dilated half an inch, child's head in second position. Pains continued four hours more, when the child was delivered. A caput succedaneum was present but disappeared within twenty-four hours. There was then seen on the site of the left parietal bone a fluctuating tumor covering its whole extent. The skin presented its natural appearance. Cold lotions and spiritous washes were applied but to no avail in diminishing the size of the tumor. Compression also failed. He next aspirated the tumor and drew off two ounces of very dark sanguineous fluid, then applied a compress, which was removed at the end of three days, revealing a healthy normal condition. The cephalhæmatoma was attended with pain, as the child cried almost continuously.

PARALYSIS AGITANS.—Professor Brandes, of the General Hospital at Copenhagen, writes to the *Gazette Médicale de Paris* that he has cured two recent cases of paralysis agitans by the continuous application of cold to the back of the neck. In older cases the method failed.

CONVALLARIA MAIALIS.

THE RESULTS OF CLINICAL EXPERIMENTS AT THE ROOSEVELT HOSPITAL, NEW YORK.

BY HENRY LING TAYLOR, M.D.,
LATE HOUSE PHYSICIAN, ROOSEVELT HOSPITAL.

My attention was first called to the drug, convallaria maialis, by an article by Dr. E. P. Hurd, of Newburyport, Mass., which appeared in THE MEDICAL RECORD of September 9, 1882. Soon after I was requested by Dr. Francis Delafield, then attending physician to Roosevelt Hospital, to give the convallaria a trial in cases which should seem appropriate. Convallaria was accordingly employed, under Dr. Delafield's direction, in the medical service of the hospital, almost to the exclusion of digitalis, in cases needing a heart tonic, from the middle of September, 1882, to the end of November. The cases in which the convallaria was employed were :

First.—Cases of Bright's disease, where the circulation seemed at fault. Six cases.

Second.—Cases of deficient circulation from organic cardiac disease. Five cases.

Third.—Cases of heart failure from pneumonia in old people. Two cases.

Fourth.—Cases of heart failure in typhoid fever. Five cases.

Fifth.—Two cases of emphysema and bronchitis (one of them with asthma) where the pulmonary condition offered an obstruction to the circulation.

These are all the cases in which convallaria was tried during the period mentioned, with the exception of five, where, for various reasons, only a very few doses were given.

The preparation used was the fluid extract of the flowers, furnished by Messrs. Parke & Davis, except from the period from October 5th to October 7th, when a specimen procured from Eimer & Amend was employed. It may be proper to state here that, so far as I know, Parke & Davis's preparation is as yet the only reliable one furnished in this country, and I am informed that their material is nearly or quite exhausted, and cannot be replenished until a new stock is collected next season.¹

The dose employed in these experiments varied from $\mathfrak{v}$ v. t.i.d. to $\mathfrak{v}$ xx. q. 4 h., and in two cases (IV. and XI.) $\mathfrak{z}$ j. t.i.d., was given with good results, where smaller dosage failed. I think I would have had better success in several instances if I had run the dose up higher than I did. In no case were any toxic symptoms observed. Vomiting was much less frequent than in patients under fairly large doses of digitalis, and could hardly be traced to the convallaria in a single instance, as it only occurred where symptoms of chronic gastric congestion or inflammation were marked (Cases I., V., and VIII.). As before mentioned, two patients were kept on $\mathfrak{z}$ j. of the convallaria t.i.d. for several weeks with much benefit and without the slightest toxic symptom.

I will now give a synopsis of the histories of the patients treated with convallaria, leaving for the conclusion a discussion of the results. Temperatures are axillary unless otherwise stated.

CASE I.—*Chronic Bright's disease.*—Cecilia J—, aged fifty-three ; Ireland ; widow ; domestic. Admitted September 19, 1882. Dyspnoea, palpitation, cough, headache, vomiting, and œdema of legs at times for the last four months. Urgent dyspnoea, last night or two.

Present Condition.—Orthopnoea ; pulse weak and irregular ; œdema of legs. Physical examination : hypertrophy of heart ; no murmurs. Subcrepitant râles bases of both lungs.

Treatment.—Rest in bed. Infusion of digitalis, $\mathfrak{z}$ j., and acetate of potash, gr. xxx., q. 4 h.

September 20th.—Temperature 103.7° F. Urine, 1,012, alkaline, albumen forty per cent. Feels better. Digitalis and acetate of potash stopped ; given convallaria, $\mathfrak{v}$ ij. q. h.

September 22d.—Temperature normal since the morn-

ing of the 20th. Pulse slower and stronger ; breathes easily.

September 24th.—Patient entirely comfortable and able to sit up. Convallaria stopped last evening.

October 17th.—Patient has been getting along very comfortably, except for headache, which is worse to-day, and patient vomits. Ordered convallaria q. 2 h.

October 21st.—Convallaria discontinued on account of nausea.

October 25th.—Patient went out on pass and did not get fatigued.

November 5th.—Patient very short of breath and nauseated.

November 6th, P.M.—Commencing œdema of lungs. Cupped over chest.

November 7th.—Put on convallaria, $\mathfrak{v}$ x. q. 4 h. Patient is passing sixty ounces of urine a day, or more.

November 13th.—Amount of urine not increased since the 4th. Patient much more comfortable ; convallaria stopped.

November 28th.—Urine, 1,008, alkaline ; albumen, trace.

December 12th.—Patient under treatment for prolapsus uteri, no uræmic symptoms. She is very comfortable.

CASE II.—*Chronic Bright's disease.*—Mary A—, aged thirty-two ; Ireland ; married ; house-work. Admitted September 12, 1882. Has complained of dyspnoea and palpitation for seven years. Slight dry cough last six months. Two weeks ago had a creeping chill and cold sweat, followed by constant vomiting and great pain in epigastrium.

Present Condition.—Pain and tenderness over lower half of sternum. Catching dyspnoea. Poor circulation in extremities. Pulse very small and thready ; regular. Pupils not responsive. Pulse, 84 ; respiration, 26 ; temperature, 97.5, A.M. Urine, 1,016 ; acid ; albumen, 5 per cent. ; no casts found. Physical examination : Prolonged respiration at both apices ; some sonorous breathing over right lung. Heart-sounds very weak ; no murmur.

September 13th.—Put on milk diet ; bicarbonate of soda, gr. x. t.i.d., and tincture of digitalis, $\mathfrak{v}$ x. t.i.d.

¹ Vide note by Dr. Hurd in THE MEDICAL RECORD, November 11, 1882.

September 14th.—Ordered a pearl of amyl nitrite daily.

September 15th.—Tincture of digitalis increased to ℥ xv. t.i.d.

September 16th.—Condition about the same as on entrance.

Present medicine stopped; ordered convallaria, ℥ xx. q. 4 h.

September 19th.—Convallaria ℥ xv. q. 4 h. No albumen in urine.

September 22d.—Pulse about the same, though patient feels much better and breathes more easily.

September 23d.—Convallaria stopped.

September 25th.—Patient much better than on entrance. Discharged improved.

CASE III.—*Chronic Bright's disease*.—Francis W.—, aged thirty-three; Ireland; married; compositor. Admitted September 25, 1882. Feet and face began to swell four months ago. Eyesight has failed for three months. Occasional attacks of occipital headache. No nausea; no change in quantity of urine.

Present Condition.—Face pale; tongue lightly coated; appetite good; bowels regular; pulse full and regular; face, legs, and genitals oedematous. Pulse, 80; respiration, 18; temperature, 98°, P.M. Urine, 1,015; neutral; albumen, 30 per cent.; casts. Physical examination: Double cardiac impact and double first sound. Lungs normal.

Treatment.—Milk diet; convallaria, ℥ v. four times a day.

September 26th, A.M.—Urine for previous twenty-four hours, sixty-three ounces. Pulse, 80; respiration, 20. P.M.: Pulse, 80; respiration, 18.

September 27th.—Five general clonic convulsions last evening, between 7 and 11 o'clock. Morphia, chloral and bromide of potassium, p. r. n. Urine, sixteen ounces. A.M.: Pulse, 80; respiration, 18. P.M.: Pulse, 72; respiration, 20.

September 28th.—Patient maniacal; nearly blind; general pruritus.

September 29th.—U. S. solution of morphia, ʒ j., night and morning.

October 1st.—Patient doing well.

October 4th.—Oxygen, gal. v., night and morning.

October 7th.—Patient is up. Pulse goes up to 100 occasionally. Urine has averaged thirty to forty ounces since September 28th; to-day sixty ounces.

October 10th.—Pulse, 84. Convallaria stopped. Put on the syrup of the iodide of iron.

October 16th.—Patient very nervous. Pulse, 120 to-

day; it has increased in rapidity since the convallaria was discontinued.

October 17th.—Still very nervous. Ordered ℥ j. of a one per cent. alcoholic solution of nitro-glycerine, given in ʒ ij. water, t.i.d. Urine, 1,010; acid; albumen, 30 per cent.; casts.

October 18th.—Nitro-glycerine made patient dizzy; felt like falling after each dose; had a feeling of a band around the head. Nervousness has disappeared. A.M.: Pulse, 112; respiration, 24. Urine forty-four ounces. P.M.: Pulse, 108; respiration, 22.

October 20th.—At own request discharged improved.

CASE IV.—*Chronic Bright's disease—Cirrhosis of liver*.—Isabella McG—, aged forty; Ireland; married. Admitted October 27, 1882. Well up to December, 1881; after that had nausea and vomiting for two months. Swelling of feet and legs since May, and of abdomen since June. Since then urine has been diminished. No headache.

Present Condition.—Very pale; face puffy; bowels regular; appetite poor; pulse weak; cedema of legs and ascites. Pulse, 116; respiration, 24; temperature, 98.5°. Urine, 1,012; acid; albumen, 60 per cent.; granular, fatty, and hyaline casts; pus and blood. Physical examination: heart and lungs negative; liver dulness diminished; fluctuation over abdomen.

Treatment.—Pot. acetat., ʒ ss.; inf. tritic. repent. O. j. Sig., ʒ ij q. 2 h. Rest in bed; bowels kept open.

October 30th.—Abdomen measures forty-one inches.

November 1st.—Acetate and triticum stopped.

November 6th.—Patient about the same. Put on fluid extract convallaria, ℥ x. q. 4 h.

November 9th.—Nausea and sleeplessness.

November 13th.—Abdomen forty-one inches. Convallaria, ℥ xx. q. 4 h.

November 17th.—Convallaria, ʒ j. t.i.d.

November 20th.—Abdomen forty inches. Feels better and passes more urine. Has a uterine fibroid size of child's head, or larger.

December 12th.—Still on convallaria, ʒ j. t.i.d. Averages about thirty ounces of urine daily. Urine to-day, 1,016; acid; albumen, 60 per cent.; casts as before. Up and about and comfortable. Urine was measured daily since entrance. Up to November 15th, the daily average was about fifteen ounces, never over twenty; after this as follows:

CASE V.—*Phthisis—Chronic Bright's disease*.—Ella W—, aged forty; United States; widow; dressmaker. Admitted July 10, 1882. Hæmoptysis two years ago. Cough for a year. Cedema of feet and legs and dyspnoea off and on for seven months. Now has anasarca below waist and cedema of right arm, dyspnoea and cough. Pulse feeble, 112; respirations, 22; temperature, 97°; urine, 1,020; neutral; albumen, 60 per cent.; granular casts.

Physical examination showed dulness over whole right lung and at left apex. Subcrepitant and coarser râles over both lungs in front and behind. Cavernous breathing at extreme left apex.

This patient went along with periods of comparative comfort, alternating with attacks of increased cedema, partial suppression of urine, dyspnoea, etc. Convallaria, ℥ ij. —iv. q. h., afterward ℥ x. q. 4 h. was tried for these attacks after September, but they seemed to run about the same course as before. The pulse and urine did not seem to be affected.

Patient died November 14th, in an uræmic attack with suppression of urine; convallaria was given up to ℥ v. q. h. in ʒ ss. of whiskey. Autopsy showed large white kidneys (the two weighed twenty-one ounces) and chronic miliary tuberculosis of lungs.

CASE VI.—Chronic Bright's disease and mitral regurgitation.—John P., aged fifty-five; Ireland; widower; longshoreman. Admitted September 20, 1882. Edema of legs for two and a half months. Worked up to a month ago, when began to have dyspnœa and feet swelled very much. At times has passed very much at other times very little urine for past two months. Constant drinker, never to intoxication.

Present Condition.—Very pale; lower limbs and genitals very œdematous; tongue clean, appetite poor. Pupils contracted and unresponsive. Breathing labored. Facial muscles twitching. Pulse feeble and irregular. Pulse, 100; respiration, 32; temperature, 100, P.M. Urine, 1,002; acid; albumen, 17 per cent. Physical examination: Mitral systolic murmur; coarse friction râles left side behind; rough breathing on right side.

Treatment.—Milk diet. Rest in bed. Fluid extract convallaria, ℥ xv., four times a day.

September 21st, A.M.—Temperature, 98.5°.

September 24th.—Pulse and urine not affected by the drug. Edema of lower limbs and dyspnœa marked.

September 25th.—Convallaria stopped; put on pot. iod., gr. x. t.i.d.

September 27th.—Iodide reduced to gr. v. t.i.d.

September 28th.—Patient very stupid. Pulse, 100–108 since entrance. Urine passed mostly in bed; about fifteen ounces daily measured.

October 2d.—Patient unconscious.

October 4th.—Died 2.30 A.M.

Autopsy by Dr. Delafield.—Large white kidneys. The two weigh sixteen ounces. Mitral insufficiency; small vegetations on aortic valve; cardiac muscle yellow, as if fatty.

CASE VII.—Mitral regurgitation.—Mary McG., aged fifty; Ireland; single; domestic. Admitted September 19, 1882, for the third time. Patient has had symptoms of cardiac disease for over three years. For a year has had dyspnœa and for eight months œdema of legs, off and on. Urine diminished at times. Present attack of œdema, dyspnœa, etc., has lasted several weeks. Is already getting better of it.

Present Condition.—Tongue clean, appetite good, bowels regular. Urine passed in fair amount. Pulse feeble, irregular, and intermittent. Pupils normal, moderate dyspnœa. Pulse, 116; respiration, 38; temperature, 98.2°, P.M. Urine, 1,018; acid; no albumen; urine contained albumen last May. Physical examination: Mitral systolic murmur. Some cardiac enlargement.

Treatment.—Convallaria, ℥ x. t.i.d. Rest in bed.

September 23d.—Patient's feet less swollen; sat up to-day.

September 24th.—Patient now has no dyspnœa and sleeps well.

September 25th.—Patient feels fairly well. Discharged improved.

This attack rather milder than previous ones, when patient recovered on digitalis.

RUPTURE OF ABDOMINAL WALLS—PROTRUSION OF STOMACH AND INTESTINES—OPERATION—RECOVERY.¹

By P. J. HIGGINS, M.D.,

WILKESBARRE, PA.

J. V., male, aged forty, Irish-American, was thrown from a locomotive over an embankment about twenty feet in height, August 21, 1879. The engine was a small narrow-gauge, working around the rolling mills of the L. I. & C. Company, at Scranton. There were seven men aboard at the time it left the rails, all of whom were more or less injured. The track ran along the edge of a bank, at the foot of which was a level space some ten feet in width. Along the level ran a second track, and some eight feet below flowed a broad and shallow stream. Of the men injured, two jumped off when the engine became derailed, and escaped with a few bruises; one went over with it and was thrown into the creek, while the others were thrown off only when it capsized upon the level. One of these latter had his foot so badly injured that amputation had to be performed; another walked home, but was injured internally and died that night; a third had serious scalp wounds, while the fourth was found lying insensible beside the wreck. To this patient, Dr. L. Wehlan was called, who requested my assistance.

When the clergyman had administered the last rites of the Church, we examined the patient's injuries and found a transverse rupture of several inches in the epigastrium, through which a large portion of the inflated stomach was protruding. Orders were given to take the injured man to his home, a distance of more than half a mile. As there was no conveyance at hand (the Act of Assembly requiring the maintenance of ambulances at mines, etc., was not passed till the following session) a broad board was picked out of the mud by the roadside, the patient was placed thereon, and carried by loving hands as tenderly as possible. We went on ahead to make some simple, hasty preparations.

The patient was placed upon a high table in a good light, his clothing cut away, and his injuries more thoroughly examined. The rent in the epigastrium measured about four inches. There was another rent, of over six inches, stretching in an irregular line from the descending arch of the colon nearly to the crest of the ilium, through which a knot of about twenty inches of intestine was protruding. There was also a scalp wound of the vertex, severe, but not considered serious.

The injuries were desperate—besides, others were, as a matter of course, suspected to exist internally, and no hopes of recovery were held out. The indications were to wash clean both stomach and intestines, carefully return them to the abdominal cavity by gentle manipulation, sew up the rents, and combat the liability to peritonitis by full doses of opiates. As the patient was unconscious, no anæsthetic was administered. A solution of chloride of sodium in tepid water—temperature, about 100° Fahr., was prepared, the stomach washed clean by squeezing the solution upon it from a sponge, and then reduced by the gentle yet firm pressure of palms and fingers over its whole extent. The pressure of gas within the organ was quite strong, and great care was necessary to maintain the reduction and prevent wounding the viscus when introducing the sutures. This was done by constant pressure of the open hand, and the insertion of the finger between it and the parietal layer of the peritoneum, when taking the stitches. Commencing at both ends of the rent at the same time, to insure an exact coaptation of the lips of the wound, four interrupted sutures of stout silk, doubled to prevent cutting through, were inserted and drawn tightly. The edges were torn, but not ragged, and were readily brought together. It was promptly decided to include the parietal layer of the peritoneum in inserting the

(To be continued.)

¹ Reported to the Luzerne County Medical Society, January 10, 1883.

sutures, so as to have two serous surfaces in contact, in order that adhesive inflammation might, in a few hours, be set up and the cavity of the abdomen again securely sealed. This was considered the cardinal and all-important point in closing the wound.

It is a serious matter to drive a needle and pull a suture through the peritoneum, usually so exceedingly sensitive to injury, especially to puncture. But experience has shown that when two injured serous surfaces are closely and firmly applied, an abundance of lymph is quickly exuded, and adhesions are rapidly formed. Much trepidation is usually experienced by the young surgeon—the old surgeon occasionally ditto—in operations involving the peritoneum, lest he should not promptly recognize this membrane when he reaches it. But in its natural condition it is very difficult to mistake the smooth, glistening tissue of slightly bluish satiny sheen for any other.

By gentle and steady manipulation for several minutes, the protruded intestines—in which the well-filled lacteals showed beautifully—were reduced, inch by inch, and the edges of the rent approximated. Commencing at both ends at the same time as before, eight interrupted sutures were inserted with the same precautions. One good feature, so far, was the absence of bleeding, or oozing from the wounds, even from the insertion of the needles. Altogether, as far as could be observed, scarcely two grammes of blood had been lost during the operation. In order to prevent the intra-abdominal pressure from tearing the stitches, two large strips of clean linen were folded into pads, or compresses, and placed over the lines of union, while, to keep them in place and supply counter-pressure, a broad piece of sheeting was doubled and applied round the trunk, from the hips to the armpits, drawn tightly and firmly secured by safety-pins. The bandage over the pads was saturated with carbolized oil. One stitch secured the scalp-wound.

In less than five minutes afterward the patient became conscious, and realized his condition and surroundings. The pulse was ninety, soft and full; the temperature normal. A quarter-grain of morphia was given, and he soon after sunk into a quiet slumber. During the operation he vomited several times, but afterward his stomach soon quieted.* Nothing was given to get rid of the intestinal gases, as the pressure and counter-pressure maintained upon the line of the wounds was considered of great service in preventing hemorrhage and hastening adhesions.

Late that night, no bad symptoms had made their appearance. Next morning the temperature was found to be 99° F., and the pulse 100. An enema of brandy and beef-tea was given, and repeated every four or five hours during the day. Majendie's solution was substituted for the morphia, and enough given to control pain, but not to maintain narcosis. The second and the third days went by without any symptoms of peritonitis appearing. The temperature at no time rose above 99° F., and the case progressed without a single untoward symptom. Three weeks after the accident the patient was able to sit up, and soon after was considered convalescent.

Here were two extensive rents made in the parietal layer of the peritoneum, while at least sixty square inches of the visceral layer were exposed to the atmosphere for over half an hour, and freely manipulated for more than five minutes. In addition to this, twenty-four punctures were made along the lines of injury. There was no spray, and no antiseptics save the carbolized oil over the dry dressings. To what is the favorable result after such fearful injuries to be attributed? And how could such injuries be produced without serious or fatal damage to internal organs? Except the wounds already noted, there was not a single scratch upon the body.

The abdominal walls were not cut, but torn clear through, as if burst, not from without, but from within. The patient was a vigorous, healthy, temperate man,

which certainly contributed materially to his recovery; but the method of inserting the sutures was undoubtedly the main factor in the case.

These were inserted in such a manner, and drawn sufficiently tight to produce a slight pouting of the lips of the wound, thus shutting off the silk from the cavity of the abdomen, which the exuded lymph, aided by the double pressure, soon sealed air-tight once more, thus preventing the entrance of pus, blood, or other irritating or foreign matters.

[In the discussion which followed, Dr. R. Davis spoke of one of his cases of ovariectomy in which the peritoneum was found united, though the patient never rallied from the shock of the operation, and died in ten hours afterward.]

A STUDY OF HERPES ZOSTER. WITH SPECIAL REGARD TO ITS ETIOLOGY.

By GEORGE THOMAS JACKSON, M.D.,

NEW YORK.

ZOSTER is a form of herpes specially distinguished by the severe neuralgic pain that usually accompanies it; by its lesions occurring in well-marked groups along the course of nerves; by being in the vast majority of cases unilateral; in rarely attacking the same individual a second time; and in often leaving scars as a sequel. It differs from the other forms of herpes in the above points, and in commonly avoiding those situations usually affected by them, viz.: the lips, nose, and genitals.

Zoster, from the Greek word meaning a belt, was so named on account of the tendency it manifests to form a belt about the body, generally a one-sided belt.

Etiology.—By the ancients, herpes was regarded as due to "yellow bile becoming fixed unmixed with other humors in a part." They taught that if the bile were thick and acrid, it would ulcerate the whole skin down to the flesh, forming what they named "*Herpes Exedens*"; but if it was thin, less acrid and hot, it would merely raise small blisters on the surface like millet seeds, and this form they named "*Herpes Miliaris*." This opinion may be found in the writings of Galen, *Ætius*, Paulus *Ægineta*, and others.

Quite early in the era of modern medicine the fact that the zoster groups were located along the course of certain nerves, and these mostly of the spinal system, led observers to surmise that there was some disease of the cerebro-spinal, or at least, the spinal nervous system at the bottom of the trouble. At last, Bärensprung, about the year 1861, originated the theory that zoster was due to disease of the ganglia on the posterior roots of the spinal nerves, or of the Gasserian ganglion of the trigeminal nerve, and since then this theory has been substantiated by himself and others. It is now held that the ganglia become inflamed, and the irritation thus set up is carried along the nerves with secondary results on the skin. In some cases hemorrhage takes place into the ganglia. The ganglia being on the posterior or sensitive roots of the nerves, their inflammation would account for the severe pain experienced in zoster. But disease of the nerve-ganglia is not sufficient to account for all the cases of zoster. This may also be caused by disease of the central nervous system, and thus can be explained the occurrence of rare cases of bilateral zoster. It may also be caused by injury or disease of a branch from the main nerve, and be limited to its distribution, or by cancerous or other deposits in the bones of the spinal column. Finally, it may result from atmospheric changes, damp wet weather, sudden arrest of profuse perspiration, poisoning by arsenic, etc.

In studying a number of consecutive cases that have been under my care, I have found in the majority of them so marked a history of mental anxiety, nervous strain or worry, as to lead me to ask myself the question: "Is not mental anxiety a too much neglected factor in the etiology of zoster?" Of course it would, no doubt, be easy

by inquiry to find anxiety and worry in a vast number of ailments, and in many cases they would be but manifestations of the physical state of the patient. But in zoster, some of my patients have given me the history of anxiety without my asking, and the anxious appearance of others has led me to the inquiry. A state of mental unrest will be found noted in four of the cases reported below. Besides these, I have recently seen two other cases having the same factor; one a married lady, enjoying usually the best of health, who was attacked suddenly with a very painful zoster after great anxiety in caring for the sick child of a friend; and the other a young man much depressed mentally while passing through the secondary stage of acquired syphilis.

Pathology.—In *Virchow's Archives*, vol. 86, part iii., 1881, Lesser ("Beitrag zur Lehre von Herpes Zoster") publishes an account of several autopsies upon the bodies of patients dying of zoster, and by microscopical examination of the affected spinal ganglia substantiates the statements made by other pathologists, a summary of which has just been given under the head of *Etiology* in this article. In regard to the secondary changes taking place in the skin, he makes the following (condensed) statement: "The principal changes are in the epidermis, first an increase in the size of the epithelial cells, each one swelling up, in some cases to even five times its usual size, and also an increase in the number of cells; probably by division (*Theilung*). Then little cavities form, containing the altered epithelium, the partition walls being composed of flattened cells; these walls at last break down and disappear, and thus the vesicles are formed. In the corium under the vesicle there is an infiltration of cells, most marked at the periphery of the vesicle. The blood-vessels are engorged, and in some places he found hemorrhages. All these changes are due to an increased nerve-supply, an increased activity in the nutrition of the cells, followed by degenerative changes, and finally, a giving way of the cells under an increase of exudation from the vessels of the corium.

The *locality* of the eruption will depend upon the nerve affected, and may be anywhere on the body, face, trunk or extremities. From the localization of the groups the varieties of zoster derive their names, which sufficiently explain themselves, as: *Zoster frontalis*; *Z. pectoralis*; *Z. dorso-lumbalis*, etc.

The *eruption* consists of groups of vesicles upon red bases, the vesicles varying in size from that of a pin-head to that of a pea, or larger, with clear, watery contents at first, becoming in the course of a few days opaque, then purulent, and at last drying into brownish yellow scabs. Each group remains intact eight to ten days, but as new groups are apt to start up, the disease may last several weeks. The vesicles in themselves do not tend to rupture, but are often broken by the rubbing of the clothing. The number of the groups is very variable. In very intense outbreaks some of the vesicles or groups may be hemorrhagic, and cicatrices are apt to remain on healing.

The *course of the disease* is acute, rarely lasting in all more than one month. The eruption is often preceded, accompanied, or followed by severe neuralgic pain, referred at times to the seat of the eruption, at times to the back, etc., as in *Z. pectoralis* we often find one painful point in the neighborhood of the spinal column, another in the axillary line where the ribs bend forward at their sharpest angle, the place of bifurcation of the anterior branch of the spinal nerve into its superficial and deep branches, and less frequently a third point near the anterior median line of the chest, where the final spreading out of the terminal branches of the nerve takes place. The pain at these points is aggravated by breathing, thus simulating the pain of acute pleuritis, the diagnosis being at times rendered still more uncertain on account of the pyrexia which may accompany the disease, but, of course, all doubt will fade away on the appearance of the eruption. If the vesicles should break, raw surfaces will be left, which by their attending pain will greatly ag-

gravate the suffering of the patient. The disease is not contagious.

Sequelæ.—In some bad cases, after the lesions proper to the disease have entirely healed, the neuralgic pain will continue for an indefinite period, or there will be lamina of certain muscles, falling out of the hair, or of the teeth. Happily such cases are rare, and the rule is that there will be no sequelæ.

Treatment.—If the patient suffers much pain, especially if his rest is disturbed by it, he must be kept quiet by the use of opium. Tonics, as iron, strychnia, quinia, etc., are to be used according to the indications present. Phosphide of zinc in doses of one-third of a grain every three hours has recently been recommended. For the neuralgic pains, especially those remaining after the local lesion has healed, Fowler's solution in fine drop doses is, perhaps, the best remedy. The constant electric current applied to the seat of the eruption and along the course of the nerves is well spoken of by Dühring, who uses five or ten cells for fifteen or thirty minutes every day, or twice a day, to the relief of the pain, both during and after the eruption, the positive pole being placed over the point of emergence of the nerve, and the negative brushed over the terminal filaments. Locally our object is to protect the delicate walls of the vesicles from rupture, and to this end it is well to use some dusting powder, such as starch, lycopodium, oxide of zinc and lycopodium; one containing morphia and camphor, etc., applied liberally, and then covered with a bandage to prevent the rubbing of the clothing. If the vesicles have burst, leaving a raw surface, powders are still useful, or some simple ointment or unguent zinc oxid, or some anodyne lotion containing opium, belladonna, and camphor, or ac. carbol, gr. 13 or 15 to the ounce of water. Morphia, gr. 10, to flexible collodion, 3 j., is also good, being painted over the part.

Below I have added the histories of five cases, illustrative of mental worry as an etiological factor in zoster, and of the disease in general.

CASE I.—*Herpes Zoster Dorso-Pectoralis*.—E. F.—, aged eight; United States. September, 1882. On the evening of September 5th the child complained of a burning pain in left side, and on the next morning the mother noticed the eruption of vesicles.

General health good. Child well nourished. No history of strain, rheumatism, or injury. Appetite good; bowels regular. Up to one year ago child had fits frequently, but none now.

The eruption is located on left side, following the course of the eighth intercostal nerve from spine to sternum. It still burns and keeps child awake. It forms an almost unbroken line of large and small vesicles, with serous contents on a red base. All the vesicles unbroken.

Was ordered a dusting-powder of lycopodium and zinc oxid, and a sleeping draught containing opium and pot. bromid.

CASE II.—*Herpes Zoster Femoralis*.—Bridget H.—, aged forty-six; Irish. October, 1881. For three or four years past she has had dyspepsia and patches of acne rosacea on nose and both cheeks. She is frequently troubled with rheumatism, but says her appetite is good, and bowels regular. She works very hard in her household cares, and for the past year she has slept badly. No history of any injury or strain.

Patient appears careworn and anxious. Acne rosacea upon end of nose and both cheeks, the patches being small. Upon the anterior and inner surface of left thigh are two groups of herpetic vesicles, the vesicles being not very closely pressed together. In the groin of same side an enlarged inguinal gland is seated. Upon touching the groups the patient complains of pain, otherwise they give her so little trouble that she came to the clinic solely on account of the enlarged gland.

A dusting powder of starch was ordered.

CASE III.—*Herpes Zoster Inguinalis*.—October, 1881.

H. C. M.—, aged thirty-three; American; no business. General history good, bowels regular, no trouble with his digestion, and no account of any injury or strain. Patient said that he knew he was "going to the devil" through his bad habits, and is very nervous and worried.

Five days ago, while in his usual health, he was attacked with a sharp pain in his left leg, and noticed a couple of patches of vesicles in his groin, since which time he has slept very poorly and the pain in leg has continued.

Patient of nervous temperament, and has a wild, worried look. Upon examination two groups of herpes vesicles are found, one immediately over inguinal glands, and the other below and to the inner side. The groups, oval in shape, upon a slightly inflamed base, are of nearly equal size, and about two and one-half inches in their longest diameter: composed of pin-head size vesicles closely pressed together, of turbid contents, and on each group one large bulla rising up prominently from about the centre.

Treatment consisted of a protecting ointment and a tonic.

CASE IV.—*Herpes Zoster Femoralis*.—October, 1881. Wm. C.—, aged sixty; Irish; no business. Patient has been dyspeptic for some time, being troubled with pyrosis, etc. Bowels regular. General health otherwise good, though he suffers from sleeplessness. No history of bruise or strain. Says he is a good deal worried by a son who leads a wild life.

Two days ago, while in his usual health, he had a severe sharp pain in the small of his back and right leg, and noticed that a number of little vesicles appeared suddenly upon his right leg. Pain in back still continues.

Patient a well-nourished man for his time of life. On examination there is found on the anterior surface of right thigh, principally in the area of distribution of the middle and internal cutaneous branches of the anterior crural nerve, six groups of herpes vesicles, varying in size, some having no more than three or four vesicles in them. Vesicles are pin-head size, with clear serous contents, the groups being seated upon reddened bases.

Treatment merely palliative.

CASE V.—*Herpes Zoster Brachialis*.¹—Mr. C.—, aged 64; butcher. August 9, 1882. His general health has always been good. About four days ago the present eruption suddenly appeared. Had been feeling unwell for a few days before, and had consulted a physician, who gave him "blue" pills, which he took on the third day preceding the eruption. The next day he had a pain on the top of his right shoulder, and felt lame there, and for this he was rubbed by his son. The next day he felt pain shooting down his arm towards the ulnar aspect, and an intense stinging in the little finger, upon which there is a scar from an old cut. On the morning of the next day noticed red spots "under the skin" on ulnar side of palm, then a group of vesicles on ball of thumb, soon followed by others on palm, and middle, ring, and little fingers. During the first twenty-four hours the eruption was confined to hand, then began to spread on wrist, and has steadily advanced up the arm, continuing most marked on its first seat. Has had no neuralgic pain since beginning, but a good deal of burning, principally in palm, and arm has felt uncomfortable when hanging at the side. Sleep undisturbed. Has never had any eruption like this before; has taken no arsenic nor other medicine of late. A son of his has recently caused him a great deal of trouble and anxiety.

Present condition.—The right hand is considerably swollen. Upon the palm are large vesico-papules mostly isolated, looking like variola eruption. Upon ulnar side of wrist the vesicles are various sized, confluent, and of light pink color. On back of wrist, hand, and ring and

small fingers eruption very well marked, consisting of vesicles, and small bullæ upon a reddened swollen base. Upon middle finger the eruption is slight, there being only one or two groups of vesicles and a few isolated ones. Thumb and forefinger perfectly free from eruption and feel natural. The eruption upon forearm and arm is more easily recognized as that of zoster, consisting as it does of numerous groups of vesicles, most of which seem at their height, seated upon red patches along the course of the internal cutaneous and musculo-spiral nerves.

He was given a placebo and cautioned against rupturing the vesicles.

September 7th.—Up to date patient has called several times, and made steady progress toward recovery, till now there are but few traces of the eruption remaining, these principally on the palm in the form of fresh skin under the ragged remains of old vesicles. The patient complains of numbness and slight loss of power in the little and ring fingers of the affected hand, an actual paralysis due probably to a neuritis. The patient now passed under the care of Dr. V. P. Gibney, surgeon to the "Hospital for Ruptured and Crippled," by whom he was originally sent to Dr. Fox, and at last report he was doing well under electrical therapeutics.

Conclusion.—It will be noticed that in four out of these five cases there was a marked element of anxiety or nervous strain, one on account of a dissipated life, two on account of a wayward son, and one from the hard struggle for existence.

These cases will also serve to illustrate the diversity in the symptom of pain. In Nos. 1 and 3, the pain preceded the eruption, was continuous for some days, and was located in the seat of the eruption; in No. 2, it was complained of only upon contact; in No. 4, it was located principally in the small of the back; while in No. 5, it was felt only just before and during the appearance of the eruption.

In all the cases there was a marked absence of any history of injury or strain of the nerve, and in but one was there any evidence of the rheumatic diathesis.

14 EAST THIRTY-FIRST STREET.

EXPERT TESTIMONY IN LUNACY CASES.—The recent trial in Chicago of a prostitute for the murder of her "lover" has forced upon public attention some serious defects in our present medical expert system. The defence took refuge in the well-tryed and old reliable plea of insanity—probably with some justice, since two most eminent and experienced neurologists affirmed its truth. "Sane," "legally sane and medically insane," "legally and medically insane," were some of the opinions offered by various experts. In a recent paper, before the Chicago Medical Society, Dr. D. R. Brower presented a caustic criticism of the judicial proceedings whereby Mark Gray was recently released from an insane hospital. Gray acquired considerable notoriety some years ago by firing several shots at Edwin Booth during a performance at McVicker's Theatre. Gray was adjudged insane by the court, and after two years' confinement in a State hospital was released, in spite of the opposition of the medical officers of the hospital, by a judge in a distant part of the State. Since his release, Gray has manifested the same delusions as before and during his confinement; in fact, he was released merely because he affirmed his own sanity.

GUAIAC IN ACUTE TONSILLITIS.—Dr. W. E. Totten, of Springfield, O., writes us that an item giving Dr. Morell Mackenzie credit for the introduction of the guaiac treatment of tonsillitis is incorrect. Dr. Totten refers to Dr. A. Patton as the original discoverer of its application in tonsillitis. He has used it many times himself with great satisfaction.

In our item we gave Dr. Mackenzie credit for recommending, not originating, the use of guaiacum in tonsillitis.

¹ I am indebted for this case to the courtesy of Prof. G. H. Fox, M.D.

Progress of Medical Science.

INTERMITTENT MANIA.—Dr. Ribas relates the case of a man who suffered from maniacal attacks occurring with great regularity every second day. The delirium was sometimes quiet, at other times violent. In the lucid intervals, beyond a slight confusion of ideas in the morning, which disappeared in a few hours, the patient was apparently rational. On his sane days he was accustomed to go about without any restraint, and no one seeing him at such times would imagine that he had been a raving maniac the day before, and would become one again the following day. Quinine in every form was employed, with no effect beyond modifying slightly the intensity of the paroxysms.—*Revista de Medicina y Cirugía Prácticas*, No. 152, 1882.

ABNORMAL PRESENCE OF URIC ACID IN VARIOUS SECRETIONS.—An excessive elimination of uric acid through various organs has been supposed to occasion a number of morbid conditions, the most generally recognized of which is gout. In many of these, however, though their dependence upon uricæmia has been strongly suspected, it has never been actually demonstrated. Dr. Boucheron now claims to have determined the presence of uric acid in the secretions of numerous patients supposed to be suffering from uricæmia, and thus to have established the relation, hitherto only conjectural, between these morbid conditions and uric acid poisoning. He has found this substance in the nasal and pharyngeal secretions, in the uterine discharges, in the sweat, in the matters vomited during morning sickness, in the menstrual blood of women suffering from uterine disorders, and in the saliva. In the last named secretion especially, he found uric acid in abundance in the various forms of uricæmia, by whatever cause excited.—*Journal de Médecine de Bruxelles*, Vol. 75, 1882.

SIGNIFICANCE OF ALBUMEN IN ASCITIC FLUID.—Professor A. Hoffman states that the amount of albumen in the fluid of ascites is of diagnostic import. He divides cases of this condition into three groups, as follows: 1. So-called cachectic ascites (especially that occurring in chronic nephritis). In this form the fluid contains over 2.5 per cent. of albumen, and has a specific gravity of less than 1010. 2. That which is known as inflammatory ascites, in which there is over 2.5 per cent. of albumen and a specific gravity exceeding 1014. 3. Ascites from obstructed circulation, which occupies a position between the first and second groups. He relates a case of ascites occurring with albuminuria, which, from the amount of albumen in the exudation and the specific gravity, seemed to conflict with this classification. But after death, it was discovered that the patient had cancer of the liver and stomach, so that the ascites really belonged to the form from obstruction, to which the amount of albumen and specific gravity would consign it.—*Allgem. Med. Central-Zeitung*, December 16, 1882.

DIPHTHERIA OF THE BLADDER WITHOUT INFECTION IN A RABBIT.—In order to determine the time within which fibrinous casts appear in the urine in retention of this fluid, Dr. Aufrecht instituted some experiments in a rabbit. The prepuce was closed with adhesive plaster, so as to cause absolute retention. This was removed after twenty-four hours and the urine analyzed. The process was repeated four times, each time retention being continued for twenty-four hours. Shortly after the rabbit died. Upon the mucous membrane of the bladder were found several patches of a dirty gray color, resembling exactly diphtheritic false membrane. Under the microscope was seen a large number of micro-organisms, some round and some rod-shaped. The rods were either single or in pairs, and often were united in a long chain. The urethra presented a normal appearance. From this experiment Aufrecht concludes that bacteria of disease

may be developed in the bladder without, as has been hitherto supposed, gaining entrance through the urethra. The condition of the canal in this case, he states, precluded any such source of infection. He thinks that this lends weight to the theory of Billroth and others, that the bacteria existing normally in the tissues may, under proper conditions, develop into noxious organisms. But, especially, he thinks that it confirms his previously expressed opinion, that it is not the mere presence of bacteria, but their retention and development in the organs, that give rise to infectious diseases.—*Allgem. Med. Central-Zeitung*, December 13, 1882.

HÆMOPTYSIS DEPENDENT UPON HÆMORRHOIDS.—Dr. Lewin recalls the views of the older writers as to the relationship existing between hemorrhoids and attacks of bleeding from the lungs. He relates two cases occurring in his practice in which hæmoptysis took place. There was no cough, and physical examination by himself and others gave absolutely no signs of bronchial or pulmonary disease. In both cases the hemorrhage was considerable, yet both recovered without any subsequent lung affection. Both patients suffered from hæmorrhoids. Lewin thinks that many cases of hæmoptysis, without apparent cause, may be thus explained. He argues that in a hyperæmic condition, such as hæmorrhoids, if local bleeding do not occur, the distended circulatory apparatus must be relieved by vicarious action. He instances some observations of Rühle, in which hæmoptysis in hæmorrhoidal subjects was arrested by leeches applied to the anus.—*Berliner Klin. Wochenschrift*, December 18, 1882.

PERFORATING ULCER OF THE STOMACH IN A CHILD.—Only five cases of perforating gastric ulcer have hitherto been published as having occurred in children. Dr. Julius Eröss, of Buda-Pesth, publishes a sixth. It was observed in a twelve year-old girl, who was suffering from miliary tuberculosis. At the post-mortem three circular ulcers were found occupying the posterior wall of the stomach. The largest, having a diameter of one inch, had perforated into the omentum. The presence of these ulcers had not been suspected during life, but inquiries instituted after the death of the patient elicited the fact that she had been suffering for a year from pain in the region of the stomach, which occurred at irregular intervals and lasted for hours at a time. Her appetite had steadily decreased, but at no time had there been either nausea or vomiting.—*Orcosi Hetilap*, December 24, 1882.

TREATMENT OF WHOOPING COUGH WITH EUCALYPTUS.—Dr. Witthauer reports four cases of pertussis, treated with tincture of eucalyptus globulus, which recovered in a little over three weeks. The dose for children from two to four years of age was 5-8 drops. One of the patients, eighteen months old, suffered from well-marked rickets. After taking the eucalyptus for four weeks, not only was the whooping cough cured, but the enlarged epiphyses were reduced, and the child, who had never before attempted to stand on its feet, learned to walk.—*Memorabilien*, November 15, 1882.

VERTIGO AS A REFLEX SYMPTOM IN HYPERTROPHY OF THE TONSILS.—Dr. Weiss relates the case of a boy, twelve years of age, who had suffered from vertigo for three years. The attacks were induced by stooping, and were sometimes accompanied with vomiting. Nothing abnormal could be discovered in any of the organs, except an enlargement of both tonsils. As pressure upon the carotids and vagi might account for the vertigo, in the absence of any other apparent cause, Dr. Weiss amputated the tonsils. The attacks at once ceased.—*Memorabilien*, November 15, 1882.

TRANSFUSION OF AN ALKALINE SOLUTION.—Dr. Bischoff has injected a six per cent. solution of chloride of sodium, a little potassa being added, into the radial artery of a woman sinking from post-partum hemorrhage.

The operation lasted an hour, during which forty ounces of the solution were injected. The woman recovered. The following are the conclusions of the author regarding this operation: 1. As compared with transfusion of blood, it is more simple, less dangerous and of more easy application, because of the difficulty of finding a donor of blood in every case. 2. The quantity of solution injected should be not less than a pint. 3. The fluid should be injected into the arteries rather than the veins, as thus it is made to traverse the capillary system before reaching the heart. It acquires a proper temperature, and the danger of sudden cardiac distention is averted.—*Journal de Médecine de Paris*, December 2, 1882.

EFFECT OF STRYCHNINE UPON DILATATION OF THE HEART.—Professor Maragliano formulates the results of the exhibition of strychnine in cardiac dilatation, as follows: 1. In one or two days the size of the heart was reduced, and in five or six days very considerable dilatations were caused to disappear. 2. If, immediately upon a reduction in size of the heart, the strychnine were withheld, the dilatation was frequently reproduced. 3. The daily dose of sulphate of strychnine required was from $\frac{1}{32}$ to $\frac{1}{20}$ grain.—*Memorabilien*, November 15, 1882.

SALICYLIC ACID IN NIGHT-SWEATS.—The following powder is recommended by Dr. Köhnorn in the night-sweats of phthisis: Acid. salicyl. gr. 45, starch, 52½, chalk, 52½. The entire body of the patient is dusted with this powder at bedtime. The author claims to have obtained great success by this treatment. The same powder is employed in the Austrian army in sweatings of the feet.—*Memorabilien*, November 15, 1882.

TINCTURE OF COBWEB IN INTERMITTENT FEVER.—In an analysis of a large number of cases of intermittent fever treated with the tincture of cobweb, Dr. Oliva formulates the following conclusions: 1. This agent is capable of curing malarial fevers of quotidian or tertian type. It was of no value in several cases of quartan fever. 2. In doses of 30 minims for adults and 15 minims for children, it usually arrests the fever at the second paroxysm. 3. Its action being less prompt than that of quinine, it should never be used in pernicious fevers. 4. Being tasteless, it is easily administered to children.—*Journal de Méd. et Chir. Pratiques*, December, 1882.

CAFFEINE IN HEART DISEASE.—Dr. Huchard claims excellent results in the treatment of cardiac dropsy by caffeine. He begins with a dose of 7 grains, gradually increasing to 15, 30, or even 45 grains per diem. He says, however, that such large doses often cause severe pains in the stomach.—*Archives Générales de Médecine*, December, 1882.

THE PATHOLOGY OF DEATH FROM BURNING.—Zillner has published more extended reports of the examinations made by him of the corpses of those who perished in the burning of the Ring Theatre, in 1881. All the bodies, even those which exhibited no external marks of injury, were more or less covered with a thick layer of soot. The upper extremities were strongly abducted from the shoulder, the elbows were bent, and the forearms pronated, so that the backs of the hands lay near the face. A fighting attitude was thus simulated in some cases. This was due to shrivelling, and consequent shortening of the muscular fibres, by the action of heat. The large cavities, and more especially that of the abdomen, were often burst, even in bodies not otherwise much injured, and the bowels protruded. In females, the tympanic state of the abdomen frequently simulated a state of pregnancy.

The blood showed every grade of consistency, from the normal, through the viscid state, up to a completely friable dry mass, in which last condition the blood-pigment was found to be in an insoluble state. Occasionally, the blood formed a dull lustrous mass in the uninjured

heart and blood-vessels. Examined spectroscopically, the blood always showed the bands of carbonic-oxide-hæmoglobin, even in the case of bodies which had remained buried beneath rubbish for a month. In all the bodies which were incinerated, the heart was found in diastole, and rigidly distended with clotted blood. This sometimes gave rise to a suspicion of concentric hypertrophy; but the thin walls of the organ at once revealed the nature of the appearance.

The bones exhibited every stage of burning, from a simple combustion up to complete calcination. The jaw was mostly firmly closed. The muscles, where the skin was unbroken, had a boiled appearance; but, where they were charred, the odor was that of smoked meat. The drying up of the flesh, and its permeation by pyrogenous products, obviously retarded the advent of putrefaction. In the eye, the application of lower grades of temperature manifested itself as a turbidity of the cornea, and complete opacity of the lens, giving the appearance of cataract. The larynx, trachea, and nostrils, were often filled with foreign material from the stomach, perhaps due to the vomiting excited by carbonic oxide. The urinary bladder was often full of urine, even when the abdomen had burst. Occasionally, where the bladder was empty of urine, it contained a gelatinous substance with embedded blood-corpuscles. This was found by E. Ludwig to consist of gelatin, probably derived from the connective tissue by the action of heat. Similar gelatinous masses were found in the uterus in some cases; and this organ was found to be very resistant to the action of heat.—*London Medical Record*, December 15, 1882.

EPILEPTIC PHENOMENA IN ATAXIA.—Vulpian (*Revue de Médecine*, No. 2, 1882) relates the case of a man, aged twenty-eight, who, in the course of a few months, had repeated attacks of loss of consciousness, with, on one occasion, right-sided facial paralysis with aphasia, and, a month later, right-sided hemiplegia and aphasia, with feeling of laryngeal constriction. All these symptoms disappeared later on, and decided tabes made its appearance. He had marked gastric and laryngeal crises, also contraction of the lower extremities, and tremulous movements, as if the lateral columns were involved. There were no knee or foot phenomena. Later, special groups of muscles, especially the abductors of the thighs, became weak, but were improved by faradization. Then the knee-joint swelled and filled with fluid; later on, the affected joints crepitated. The question of the rheumatic or specific nature of this joint-affection is discussed. The patient benefited greatly by bromide of uranium in doses of one-sixtieth to one-fifteenth grain daily, especially in respect to pain.

CEREBRAL SYMPTOMS PRODUCED BY ASCARIS LUMBRICOIDES.—Dr. Samada reports (*El Sentido Católico en las Ciencias Médicas*) a case in which severe symptoms were produced by the presence of a large number of ascarides lumbricoides. The patient was a lad about eight years old. His attack commenced with severe headache, attributed to a fall sustained a few days before. This was followed by photophobia, conjunctival injection, and later by profound coma. Constipation was present, and, as a saline purgative did not produce an evacuation, calomel and aloes were administered. This produced several evacuations, each containing about thirty ascarides. The head-symptoms ceased from the moment the bowels were purged, "as if by magic."

PATHOLOGICAL ANATOMY OF GENERAL PARALYSIS.—Dr. Rey has found (*Ann. Méd.-Psychol.*), in fifteen brains of general paralytics, separation of the cortex from the underlying white matter, as described by M. Baillarger. Dr. Rey relates six of his observations in detail. It is remarkable that he should have found this lesion existing only in the frontal lobes, whereas the former writer described it as most common on the posterior lobes of the cerebrum.

ACTION OF IODOFORM ON LEUCOCYTES.—Dr. Binz (*Virchow's Archiv*, vol. lxxxix., 1882) has performed some experiments which would seem to show that iodoform checks suppuration by paralyzing the white blood-corpuscles, and so preventing their wandering through the walls of the vessels. He maintains that quinine, and carbolic and salicylic acids, have a similar effect.

DISGUISED SYPHILIS.—In an article on this subject (*Medical and Surgical Reporter*, September 30, 1882), the importance of remembering that syphilis is not of necessity a venereal disease is insisted on. In illustration, a case is related of a lady who, when two months pregnant, received into her family a young female relation who had been brought up in Germany. This relation was suffering from an eruption on the scalp, which was dressed by the lady, who subsequently noticed that a pin-scratch on her finger became inflamed and angry-looking, and in a short time a nut-like swelling appeared on the inner aspect of the elbow. Afterward she began to lose flesh; her appetite failed; the throat became sore; she suffered from headache and debility, and albumen appeared in the urine. The patient quickly recovered under bino-dide of mercury and iodide of potassium.

CONGENITAL ABSENCE OF THE SPLEEN.—At the City Hospital of Buda-Pesth a woman, aged seventy, recently died. At the post-mortem examination it was ascertained that the spleen was entirely absent. Since the complete destruction of a previously existing spleen could be excluded, it was concluded that her case was an instance of congenital absence of this organ.

SUGAR OF MILK AS A LAXATIVE.—Traube recommends sugar of milk as a mild and trustworthy laxative in doses of two or three drachms, dissolved in half a tumbler of warm milk, taken before breakfast.

THE ALBUMINURIA OF FEVERS.—Dr. Eckstein distinguishes three varieties of albuminuria accompanying the febrile state (*Deutsche Medizinische Wochenschrift*): First, albuminuria caused by acute nephritis; second, the so-called febrile albuminuria; and third, albuminuria caused by venous hyperæmia. The last form, in which the urine is small in quantity and of high specific gravity, occasionally containing casts and renal epithelium, is diagnosed mainly by the presence of other symptoms pointing to venous hyperæmia, such as cyanosis, enlargement of the liver, and dyspnoea. The author opposes the belief that venous hyperæmia is the sole cause of albuminuria in febrile disease. He believes that it is responsible for the albuminuria occurring in acute croupous pneumonia, and in rapidly formed pleuritic effusion, the local affection acting mechanically, first on the right side of the heart, then on the venous system generally. Acute nephritis Dr. Eckstein believes to be a metastatic inflammation, an infective process, in which the micro-organism, although it has not yet been demonstrated, as in kidney affection from diphtheria or pyæmia, will at no distant date be isolated. The result of acute nephritis is either complete recovery or death, very rarely chronic nephritis.

In the so-called febrile albuminuria, which Dr. Eckstein mainly considers, the amount of urine is but slightly diminished, according to the severity of the fever itself; the amount of albumen is moderate, and the normal excretory constituents of the urine are not diminished. That the albuminuria in such cases is caused by hyperæmia of the kidney, either active or passive, seems to Dr. Eckstein improbable. For the first result of a congestive hyperæmia would be an increased amount of urine which is not present; and on the other hand, there is no reason to suppose a passive hyperæmia, except in such cases as have already been classed under albuminuria from direct venous congestion. Runeberg has lately explained the diminished secretion and albuminuria in febrile diseases by the degeneration of the heart-muscle

and consequent fall of arterial tension. But, as Dr. Eckstein points out, in many diseases where the arterial tension is reduced to a very low point, there may be absolutely no albumen in the urine. That the albuminuria is caused simply by the abnormal temperature, or by an alteration of the albumen of the blood, is not, Dr. Eckstein believes, supported by fact. For the albuminuria is frequently in no relation whatever to the temperature, and the albumen in the great majority of instances in no way differs from the serum albumen of the blood.

Dr. Eckstein sums up his views as follows: Febrile albuminuria depends on a local process in the kidneys of an inflammatory nature, or at least closely related to inflammation, and having its site mainly in the epithelium of the kidney, cloudy swelling, albuminous infiltration, or parenchymatous inflammation. This process is probably caused by an infection of the kidneys, either from the passage through them of low parasitic organisms, or from the inflammatory action of soluble toxic substances passing through them. The same infection acting in a stronger degree can produce acute nephritis. Acute infective nephritis, therefore, and febrile renal affection, are only different degrees of the same process, or, in other words, the febrile renal affection is an aborted acute infective nephritis.

HÆMOPHILIA.—Dr. Thos. D. Dunn reports a number of cases of this disease in the *American Journal of the Medical Sciences* for January, 1883, from which he draws some interesting conclusions. Thus, he shows that sex is an important predisposing cause in hæmophilia, females being much less prone to the disease than males, and in women, also, the danger to life is much less marked; the females, however, of bleeder families, even though themselves exempt from the disease, are much more apt to transmit the tendency to hemorrhage to their children than are the males, even when themselves bleeders. Dr. Dunn also points out that there are three forms of the disease: 1. The aggravated form, in which there is a tendency to severe spontaneous, traumatic, and interstitial hemorrhages, associated with swelling of the joints. This form, seldom seen in females, generally lasts throughout life, and usually is the cause of death. 2. The intermediate form has no tendency to the joint affection or traumatic hemorrhages, but frequent spontaneous ones from mucous surfaces and subcutaneous ecchymoses. This form frequently disappears at puberty. 3. The third form is lowest in degree, and seen only in females; it manifests itself in ecchymoses, and in early and prolonged menstruation.

MALARIA OR SEPSIS.—Dr. W. B. Welch, of Fayetteville, Ark., writes us as follows: In vol. xxii., No. 22, p. 608, of THE MEDICAL RECORD, a case, entitled "Per-nicious Remittent Fever after Parturition," is detailed by Dr. J. Lewis Smith before the New York Academy of Medicine (Obs. Sec.). I have read with pleasure Dr. Smith's report of the case, and must say that I, and I believe many others, will differ with him as to his diagnosis of the case. A case of malarial fever, where the patient survived eighteen days, and in which from thirty to sixty grains of quinine were given *per orem*, and ten grains of quiniæ et urææ muriatis given hypodermically every twenty-four hours! All this time the temperature rising higher and higher with each daily paroxysm, and the *sweatings* becoming more and more copious and exhausting. Those of us who have much to do with malarial fevers may be pardoned for being slow to believe that quinia would be so very little efficacious in so *prolonged an opportunity* in any case of malarial toxæmia. More especially are we led to so conclude from reading Dr. Smith's case, as we think there can be no doubt that his was a case of very malignant puerperal sepsis or pyæmia—in fact, *classical* in its distinctness of detail and marked symptomatology.

THE MEDICAL RECORD:

CHARCOT'S CRYSTALS AND THE ASTHMATIC PAROXYSM.

It will be remembered that, in 1872, Leyden announced his discovery in the sputa of asthmatic patients of peculiar crystals, first described by Charcot and Robin. The bodies seen by Leyden were colorless, rather long, octahedra, of varying size. They were found mixed in little plug-shaped masses with brownish granular cells. He thereupon advanced the theory that asthma arose from an irritation of the terminal filaments of the vagus in the alveoli and bronchioles. This irritation, he claimed, was directly attributable to the presence of the fine sharp crystals in question. Leyden's theory met with little favor at the time, and few subsequent writers have made mention of his discovery.

The subject was revived, however, at the first Congress of German Physicians, held in the spring of 1882. Dr. Ungar, of Bonn, there read a paper embodying his views of the causal relation of those crystals to the asthmatic paroxysm. He found the crystals present in the sputa in every one of thirty-nine cases of spasmodic asthma examined by him. And he determined further that they were not always present in fresh sputum, but were formed after keeping the expectorated matter for two or three days in a moist atmosphere. The longer the sputa were preserved, the more numerous and the larger were the crystals. In the course of his investigations the author also discovered other objects in the expectorated matter. These were long thread-like masses, sometimes stretched out like strings, and at others matted and twisted up into little balls. They were composed, like the plugs described by Leyden, of granular cells, and in fact the plugs were but detached fragments of these slender cylinders. The corpuscles in the centre of the cylinders were more granular and less distinctly outlined than those at the surface. Moreover, it was precisely in the centre, where the disintegration of the cells was most advanced, that Charcot's crystals were found in greatest abundance. Hence Ungar concludes that these bodies occurring in the sputa of asthmatic patients are the product of cell-degeneration, just as those found in leucæmic blood were proved to be by Zenker.

But, though rejecting Leyden's theory, Ungar does not admit the generally accepted neurotic nature of the asthmatic seizure. He explains the paroxysms of dyspnoea in this wise. The larger bronchi, as is well known, are firm unyielding tubes. But as we pass down to the

smaller branches, the cartilages gradually disappear and we find only a thin wall of fibrous tissue mixed with slender muscular elements, and lined by a mucous membrane. Now, the lumen of the bronchioles is constantly varying in size with the movements of respiration. Expansion is due to the suction action of the thorax in inspiration, and the subsequent contraction to the inherent elasticity of the walls of the bronchioles. The muscular fibres serve merely as stays to prevent overstretching of the elastic tissues. They can never act with force sufficient to produce a spasmodic constriction of the tubes. Now, when a plug of this exudation completely occludes a bronchiole at rest, during inspiration the calibre of the tube is increased and air may pass the obstruction. But as soon as the suction force of the chest-walls is relaxed, the bronchiole returns to its former size and the air is imprisoned.

This valvular action may also be called into play in the following manner: The exudation at times consists of a number of fine filaments composed of agglutinated cells and crystals too small to block up the bronchiole. These threads are attached to the wall of the tube by one extremity only. Now, during inspiration they float freely in the entering air-current, offering no serious obstacle to its passage. But, during expiration, when the current is reversed, these strings are pushed back and twisted up into little balls, thus thoroughly obstructing the return of air. In this way an acute emphysema, as it were, is produced by a sort of reversed air-pump action. And now the asthmatic paroxysm is ushered in. The depression of the diaphragm is merely a result of the expansion of the lungs and plays no part whatever in the causation of the dyspnoea. Dr. Ungar's theory is, to say the least, a novel and ingenious one. But, like many other well-reasoned hypotheses, it needs some substantial confirmation before it can hope to meet with any general acceptance.

THE MICROSCOPICAL APPEARANCES OF GUITEAU'S BRAIN.

THE editor of the *Journal of Mental Science*, Dr. Geo. H. Savage, makes the following comment upon the microscopical appearances observed in a section from the frontal convex of Guiteau's brain: "I should say there is nothing that I have seen which is not compatible with mental health. It is true there are changes about the vessels and their walls, but these and similar changes are commonly found in the bodies of persons dying or being killed when past middle age. There are no marked general changes in the nerve-cells, and I can only repeat that the specimen examined would not have any weight with me, in causing me to reconsider my judgment on the sanity of the assassin."

The facts seem to be, that while there was some chronic disease in and about the blood-vessels, there was nothing indicative of any form of insanity; while, on the other hand, much more serious changes are not infrequently found in the brains of persons who had been perfectly sane. Account must be made also of the fact that Guiteau had been suffering from malarial poisoning, and that he suffered death from strangulation. Guiteau's insanity, if it existed, was confessedly chronic; therefore

all acute changes found, would have no weight in estimating their etiological bearings on the alleged mental disease. The severest form of the vascular disease was apparently the corpora striata, a place where physical troubles would not be excited, while it is well known that the disease did not disturb any function known to pertain to those ganglia.

The view that the changes found were at all significant or characteristic of commencing general paresis is unfounded, and quite unworthy of serious discussion. The same remark must be made regarding Dr. Godding's surprising statement that the arachnoid's opacity was indicative of mental disease.

There have been some rather labored attempts to prove the brain atypical. The convolitional development, however, as we are told, though deficient in some parts, was compensated for by fuller adjacent gyri. So far as the eye and some rough measurements could tell, the two hemispheres showed no asymmetry. The fundamental fact in the present case for the determination of atypy, viz., the comparative weight of the two hemispheres being absent, it would not be allowable nor in accordance with scientific honesty to make positive statements regarding the matter.

The futile and decidedly *ex-parte* attempt to show pathological cranial asymmetry hardly needs comment. In fact, Guiteau's mental condition must be decided by a study of his words and actions when alive. If these did not prove him a lunatic and irresponsible, the post-mortem findings will not help the case.

THE QUESTION OF WOMAN'S DRESS.

WOMAN'S dress furnishes periodically a valuable topic for the preacher, the satirist, and the physician. Just at present it is medical opinion which in particular is being luminously offered upon the matter. The *Lancet* speaks paternally to British women, and tells them not to hang so much on their hips during the present cold weather. The *New York Times*, taking up the subject, has sent a reporter to various large retail stores where ladies' dress and undergarments are sold. Samples of these were carefully weighed, and their modes of attachment to the female anatomy studied. The reporter subsequently interviewed a number of physicians upon the important and obscure matter of how woman should best wear her clothes.

From all this we learn that woman's winter clothes weigh from six to ten pounds, and that she carries a heavier weight than man by one-fourth or one-third. It is noted also that this weight when hanging from the hips, constricting the waist and confining the legs, does harm.

We are inclined to believe that the constant reiteration of the charges against woman's dress, together with the wider diffusion of physiological knowledge, is having some slight effect upon woman's dress. It is all the more important that medical opinions given regarding it should not be sensational or incorrect. Little good is done, for example, by wholesale denunciations of the corset *per se*, when they should be directed rather against those which are tight and ill-fitting. So as regards the wearing of clothes upon the hips. The hips of women most naturally and easily support the greater part of the weight

of skirts. Care need only be taken that there be no constriction or binding. The shoulders should be allowed to do a minor part of the work. Woman's dress is, as a rule, unnecessarily heavy, but it will not be in our generation that fashion bows to sanitary rules.

OVER-WORK AGAIN AMONG AMERICANS.

THE views expressed by Mr. Herbert Spencer upon the high-pressure mode of life followed by Americans have been widely criticised. To be sure, no American medical authorities have ventured to dispute his conclusions. For Mr. Spencer has, in fact, only said again, and even unconsciously plagiarized, what American doctors have long ago noticed and publicly discussed.

Mr. Seymour Haden, however, an English surgeon and artist now visiting America, has flatly contradicted the statement that Americans work too fiercely, or live too little in the present, and too much in the future. Dr. Batty Tulse, also, in a recent public address, announced the not very original view that it is not over-work but worry which kills.

Now, the daily newspapers and English tourists may discuss glibly the *pros* and *cons* of this question, but, with practical physicians, who every day meet the business men of our cities, there is no question to discuss. Every one has seen the victims of over-work, and knows that the persistent, untiring application to business, wears men out. It may not be the work alone; there is technical truth in saying that worry, not work, is the most serious danger; or that dry air or physical neglect help on the trouble. But this is mere quibbling, for there are few who can work actively and continuously without some worry or neglect of sanitary rules.

The conditions of our life require that Americans should be more than ordinarily active and industrious, but all the same we should be a happier and healthier people for a little more of the gospel of recreations.

The lazy may seize this as an excuse, but our sanitary evangelists must say that their gospel does not apply to the lazy, who in America are greatly in the minority.

THE CARE OF PROSTITUTES IN CLEVELAND.

MUCH excitement has recently been created in Cleveland, O., by the action of the Board of Health upon the matter of the sanitary care of prostitutes. An ordinance was passed favoring the establishment of a hospital where diseased women found in houses of ill-fame should be taken and cared for, at the expense of the owner of the property. It was also voted that physicians should make weekly examinations of the women in the brothels.

This new move has been condemned by many of the citizens of Cleveland. The women especially have banded themselves together to fight against it. They insist that men, as well as women, who visit brothels while diseased, should be sent to the hospitals for treatment.

The results, so far, of attempts to regulate prostitution in American cities are well known. It must be admitted that the plan is utterly opposed to the judgment of the better and more respectable part of society. The methods adopted in Cleveland have failed elsewhere, and

will, we presume, fail here, because it is based upon a one-sided policy. It officially cares for the women after they have become diseased, but takes no notice of the men who infect them.

Many sanitarians seem incapable of understanding that the question of prostitution is not a purely sanitary one, but is a sociological problem, involving many factors. The prevention of disease is not the only element in human progress.

The establishment of lock hospitals for women is in many cases advisable and useful; but we doubt if in this country the forcible sending of women to these places will be tolerated.

Many sanitarians, although they aim to be "advanced," fail to see that as intelligence increases a private regulation and examination of brothels will largely become adopted. Adultery will follow the law of supply and demand everywhere.

We suspect that the Cleveland Board of Health has tried to be "progressive," without knowing very much about the project it has undertaken.

MICROSCOPES ON THE TARIFF FREE LIST.

THE Committee of Ways and Means at Washington are now considering the provisions of the new tariff bill, and some of their conclusions have been made public. We notice that philosophical instruments will in future pay a duty of forty per cent., an exception being made in the case of those imported for the use of institutions and societies incorporated for educational or religious purposes.

The duty on scientific instruments must yield a very small return, and be imposed only as a protective measure, to aid the home industry of such manufactures.

Desiring, as we do, that every medical practitioner should possess a microscope, not as a mere adjunct to his office, but as a necessity in making a diagnosis of many complicated diseases, we would offer a few suggestions to those revising the tariff laws, with the hope that such instruments may be in future imported free.

There is little merit in the making of the stands of microscopes, a good design being furnished, an ordinary brass-worker can carry out the mechanical part. The case is different in regard to the manufacture of microscope objections, as we find in this department that scientific knowledge and great technical skill is requisite. Spencer being dead, we have, therefore, but three really original workers, having an American reputation for making objectives, viz., Grunow of New York, Tolles of Boston, and Gundlach of Rochester. The question may be asked, would they suffer by such a reduction of the tariff as we propose? We believe not. As a matter of fact, those who require to possess an objective constructed by Tolles, have to wait from six to twelve months before receiving it. The free list will surely have no effect upon such men who are capable of incorporating their individuality in their work, and with three original manufacturers of microscope objectives and two or three of indifferent merit, ample work must be in store for them under any circumstances.

We believe that not only the medical profession, but the microscope trade itself, would be benefited by the change we propose. All purchasers would be placed on

the same footing, and colleges, with other institutions now making their selection abroad, would probably in the future give their patronage to the home manufacturers.

The discrimination proposed in favor of certain wealthy institutions is both unnecessary and unjust, for it affords relief in a direction where it is neither required nor appreciated, and doubles the cost of the instruments in the case of the poor student, or the young physician who is starting on a career calling for constant outlay and yielding small returns during its earlier stages. We understand that the proposition to place microscopes on the free list, without discriminations in favor of any class, was brought to the notice of the Tariff Commission by Mr. John Michels, and that a prominent member of the House of Representatives has promised to introduce such a resolution when the measure is discussed. There appears, therefore, some prospect that practical results may be accomplished in this direction.

TENEMENT HOUSE CIGARS.

It is not an agreeable thought for smokers of domestic brands of cigars, that the specimen they hold between their lips was perhaps manufactured in some fever den, amidst the filth and stench of an Italian tenement house. Could the purchaser of the five-cent "*regalia*" view the home of its birth, with all the surroundings of vice, dirt, and misery, he would possibly decline to kick with his foot the cigar he places in his mouth.

We notice that a Society of Progressive Cigar Makers met last Monday at the Cooper Union, to protest against the system of manufacturing cigars in tenement houses, making their appeal in the name of "health, science, and humanity." We do not pretend to explain, or even to know, the exact motives which have inspired the "Progressive" cigar makers to this crusade on their more humble fellow workmen. The proceedings, however, indicated that the reformers were "aggressive" as well as "progressive," and the taint of a trade union spite was apparent, rather than the true "Havana" odor of sincere sanitary reform.

This is clearly a case for the control of the Board of Health, and we are not surprised that the Legislature "laughed at the efforts" of the Progressive Cigar Makers. Although smoked, a part of every cigar is necessarily chewed, and the pressure of the teeth on the moistened tip must extract a certain amount of tobacco juice. Cigars, therefore, may in one sense be classed with articles of food, and a law should be passed enabling the Board of Health to prohibit their manufacture in sleeping-rooms. Such an arrangement would, perhaps, satisfy the Progressive and Aggressive Cigar Makers' Union.

PUDDINGS AND PIES.

The *Lancet* struck a most responsive chord in the British bosom recently when it announced that plum-pudding was a wholesome and nutritious article of diet. It contains, says this authority, force equivalent to two hundred and fifty foot-tons; and the opposition to utilizing such an appetizing form of energy is characterized as "middle-age prejudice."

Now what the plum-pudding is to English hearts of

oak and stomachs of similar robustness, the pie is to the American. We should, perhaps, say to the American Yankee; but this individual has distributed himself and his pies so universally that a distinction is now hardly needed. And the American pie deserves a word of encomium quite as much as the English pudding.

There is a "middle-age prejudice" also among us against pies; but it is, we are sure, quite as irrational as that against puddings. There is not quite so much potential energy in the former as in its equivalent weight of the latter. But man does not eat for the sake alone of storing up solid "chunks" of force. And certainly, there is much about the pie to make it more digestible than the pudding, if it is not quite so compactly nutritious. Out of the records of a very large clinical experience we have been able to collect no facts which prove that pie properly made ever caused dyspepsia. It is a general custom, and a wise one, to prohibit pastry and cakes and puddings when dyspeptic symptoms appear; but we should be inclined to hold on to the pie longer than to the other forms of sweetness. Dyspepsia is confessedly very common among Americans, and the ubiquitous pie has been sometimes charged with being a potent factor in these gastric ills. But only superficial philosophers will thus malign an article of diet which has brought so much real sweetness and comfort into the life of the hard-worked Yankee. Dyspepsia prevails as much among the rural populations of some Southern districts, where life is pieless, and (to Yankee apprehension) meaningless, as in the North.

In fine, pie, well-made pie, is digestible, and may be taken with impunity by those to whom plum-pudding is, peptically, a terror. If made with fruit, it is antiscorbutic; if with other materials, decidedly nutritious. Under any conditions it is more wholesome than that leviathan of culinary art the plum-pudding. Nor do we feel confident that *The Lancet's* recommendation of this latter article should be taken by Americans without great caution.

A REMEDY FOR ASTHMA.—The leaves of *euphorbia pilulifera*, L., a plant growing in Queensland, are reported to be a sure remedy for asthma and other affections of the chest.

COOK COUNTY HOSPITAL.—The capacity of Cook County Hospital, Chicago, will shortly be increased from three hundred and fifty to five hundred beds by the completion of two additional pavilions and the executive building, now in process of construction.

TROPIC FRUIT LAXATIVE is the name of a proprietary article having about the following composition:

R. Jalap tubers, powdered	5 parts.
Senna leaves	5 "
Sugar	5 "
Pulp of E. I. tamarinds	30 "

The preparation is said to be liable to get worm-eaten.

PROF. VIRCHOW is reported to be seriously ill.

TWELVE CASES OF SCURVY were recently brought to San Francisco, Cal., on the ship *Anna Camp* of New York. Investigation having disclosed the fact that the sickness had resulted from a violation of law in regard to this disease on the part of the captain of the vessel, the District Attorney of San Francisco has been instructed to proceed against him.

THE PRICE OF BOOKS.—Publishers will hereafter please state the price of books sent for review.

News of the Week.

SMALL-POX IN NEW YORK.—Two cases of small-pox were reported to the City Health Office on January 20th. These are the first cases of small-pox in the city since November 6th. The patients were living on Second Avenue, near One Hundred and Fourteenth Street.

MONEY FOR ST. VINCENT'S HOSPITAL.—The Sisters of Charity in charge of St. Vincent's Hospital report that the Fair, recently held, netted \$22,407.17.

PROFESSOR TYNDALL is lecturing at the Royal Institution, London, on "Light and the Eye."

EXPLOSIVE HYPOPHOSPHITES.—As Dr. H. Gifford, of Syracuse, was engaged recently in triturating a mixture of hypophosphite of lime, three parts, and hypophosphite of soda, one part, the compound exploded like gunpowder, the fine particles flying into his face and eyes and severely burning his eyelids and eyeballs. His injuries are likely to result in the loss of his left eye.

THE AUTOPSY ON GAMBETTA.—Further details of the autopsy on Gambetta confirm the view of the nature of his troubles which we based on the earlier and somewhat incoherent descriptions. The physicians in charge report "he succumbed to a perityphlitis, complicated by a pericolicitis, to which was added a slight peritonitis manifested during his last moments. Any surgical intervention would have been useless. It could have had no other effect than to abridge his life." The autopsy was conducted by Drs. Brouardel and Cornil, and in the presence of Drs. Charcot, Lannelongue, Gille, Fienzal, Sirédey, Trélat, Verneuil, Liouville, Mathias Duval, Laborde, Guerlat, and Gibier, who signed the report, as did also Paul Bert, who fainted during the operation.

ONE HUNDRED AND EIGHTY LUNACY COMMISSIONERS.—The spirit of lunacy reform has rather run away with itself. Gen. Spinola has presented a bill, in the State Assembly, authorizing the creation as Commissioners in Lunacy, in every county of the State, of only reputable physicians of at least twelve years' standing. For New York three commissioners are to be appointed by the Mayor, who are to receive \$5,000 salary apiece. No provision is made for the salaries of commissioners in any of the other counties. This would create one hundred and eighty lunacy commissioners. While we should be pleased to know that so large a number of our noble profession were occupying valuable sinecures, in the interests of the State we can by no means advise such a measure. It is cumbersome, expensive, and unnecessary.

SHORT-WEIGHT QUININE PILLS.—A "Commission" recently published in the *Medical News* of Philadelphia the results of examinations and analyses of quinine pills, and announced that there was very generally a short weight. Messrs. W. H. Schieffelin & Co., of New York, now state in a card that the charge is not true so far as their pills are concerned. The "Commission" in question is accused of having used a faulty method of analysis, of being guilty of mathematical mistakes and misleading comparisons. McKesson & Robbins make similar statements.

SEATS FOR FEMALE EMPLOYÉS.—A sensible bill has been introduced in the Minnesota Senate, providing for seats for all female employés in factories or stores.

A SCHOOL OF PHARMACY FOR WOMEN has been opened in Louisville, Ky.

PAY FOR THE EXPERTS IN THE GUTEAU TRIAL.—The four medical experts summoned by the Government in the Guiteau trial—Dr. Gray, of Utica; Drs. Macdonald and Allan McLane Hamilton, of New York; and Dr. Kempster, of Kenosha, Wis.—are to be paid each at the rate of \$25 per day. The total amount will reach \$13,000.

SMALL-POX IN BALTIMORE.—Small-pox, which has prevailed so extensively in Baltimore, is now said by the authorities to be under control. Vaccination is carried on by wholesale, and the new cases of variola are promptly and efficiently quarantined.

SENT TO A SMALL-POX HOSPITAL WITH MEASLES.—Dr. M. M. Walker, of Germantown, Pa., has been sued for damages by a female patient, who, having measles, was sent by him to the small-pox hospital as a case of small-pox. The diagnosis was made in the early period of the eruption. The patient recovered from the measles, suffered an attack of varioloid, the result, as is alleged, of the exposure to the disease in the hospital, and finally left the hospital cured. It was properly claimed that the mistake in diagnosis was not, under the circumstances, absolutely avoidable. Five similar instances are said to have occurred in Baltimore during the past week.

BAD DRINKING-WATER IN PHILADELPHIA.—Communications have been received by the Philadelphia authorities from the commissioners of Fairmount Park touching the impurity of the Schuylkill water. These have been referred to the Finance Committee, in order that a request for an appropriation of \$200 to make chemical tests may be properly considered.

ANTI-DISESECTION BILL.—A bill has been introduced in the Michigan legislature, providing that the bodies of unclaimed paupers shall not hereafter be sent to the Medical College at Ann Harbor for dissection. It is supposed to be inspired by some sentimental buncombe in the Governor's message. As might have been expected, the measure meets with much opposition from sensible citizens.

STATE BOARD OF HEALTH FOR PENNSYLVANIA.—A movement has been made for the establishment of a State Board of Health for Pennsylvania. A bill introduced into the legislature of that State provides that the Governor appoint six persons (a majority physicians) to inspect sanitary and public institutions and suggest amendments to the sanitary laws, and supervise the registration of births, marriages, deaths, and prevalent diseases.

A POST MORTEM ON DR. GEORGE M. BEARD was held Wednesday afternoon. It was conducted by Dr. T. E. Satterthwaite, assisted by Dr. W. H. Porter. It was found that the disease causing death was an embolic pneumonia, originating in an abscess of the upper maxilla. The right lung was, in large part, consolidated. The left lung was dark, very soft, and would soon have become gangrenous. The funeral takes place to-day (Saturday) at 11 A.M.

INSTRUCTION TO DELEGATES AND THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.—At a meeting of the Medical Society of the County of New York, held January 22d, a motion to instruct the delegates to the State Society was defeated by a vote of 31 to 9.

DR. OLIVER WENDELL HOLMES, of Boston, is about to visit England. The distinguished author will be sure of a hearty welcome.

WANTED—A NEW HEALTH RESORT.—Commenting on the fact that the West Indies has been forbidden Mr. Vanderbilt, as being too warm, the "Broadway Lounger" says: "We much need a Northern watering-place in the South less flabby than Florida, with better hotels than San Antonio, with less visible disease than Hot Springs, with more security than New Orleans, and more outlet than Fortress Monroe." Plainly, the writer can never have seen the Atlantic City newspapers, in which two or three hundred Philadelphia physicians, in good ethical standing, have endorsed that resort.

Reviews and Notices.

A TREATISE ON FRACTURES. By LEWIS A. STIMSON, B.A., M.D., Professor of Surgical Pathology, Medical Faculty, University of the City of New York; Surgeon to Bellevue and Presbyterian Hospitals. With 350 illustrations. 8vo, pp. 598. Philadelphia: Henry C. Lea's Son & Co.

THE work comes to us without a preface, and with none of the usual apologies for its publication. In most cases such apologies are needed more than in the present instance. It claims for itself nothing more nor less than can be learned from it by careful reading. The author has a thorough conception of what should constitute a practical treatise on fractures, and carries it out in a manner that must prove satisfactory to the student and practitioner. His subjects are arranged in a systematic manner, and the different mooted points in the pathology and treatment are on the whole very well discussed. In the laudable effort to be concise, he shows a tendency to drift into forms of expression which are somewhat dogmatic. Especially does this appear to be the case when the conclusions arrived at are seemingly based rather on theoretical grounds than on the results of actual personal experience. But the reader is quite ready to overlook this disposition on the part of the author, in view of the admirably exhaustive *résumé* which he gives of the experience of others. It must not be inferred, however, that our author has not improved his own opportunities for observation to the utmost. The results of these are presented here and there throughout the work in a becomingly modest manner, and independently positive form. Some of his special studies into the causes of deformities, notably those about the wrist and elbow, are of much value, showing ingenious reasoning, which has a desirably practical turn.

The subjects of repair in fractures, and the complications and remote consequences of fracture are very clearly presented, as are also the general considerations of the treatment of these lesions by various apparatus. The fractures of special bones are systematically considered in turn, and their causes, symptoms, diagnosis and treatment fully described. The illustrations, which are numerous and for the most part original, are exceedingly good. They represent all the leading features of general and special fractures, as well as most of the recognized methods of treatment for the same. Altogether it is a work which will be read with interest and profit by the student and general practitioner.

QUAIN'S ELEMENTS OF ANATOMY. Edited by ALLEN THOMSON, M.D., D.C.L., LL.D., F.R.S., EDWARD A. SCHÄFER, F.R.S., and GEORGE D. KANE. In two volumes. Ninth Edition. New York: Wm. Wood & Co. 1882.

A WORK on anatomy which has, within a comparatively short period, reached its ninth edition, scarcely needs the commendation of the reviewer. Before the fact of well-earned success, praise seems but a task of supererogation. We may briefly note, however, in what respects the present edition differs from previous issues, and whether the new Quain has taken due cognizance of the advances made in the various branches of anatomy. A critical analysis at once reveals the thoroughness with which the work has been revised. Some obsolete opinions have been entirely discarded, and wherever necessary, new matter has been introduced. Nevertheless, while material alterations were thus made, the original form of the book has been retained.

One of the best features of the new edition is the excellency of those portions which relate to embryology, histology, and the cerebro-spinal system. These branches are, as a rule, so inadequately treated, even in standard text-books, that it is a pleasant surprise to find them fully up to date in the work before us.

The illustrations are satisfactory throughout the volume, and the edition contains many new ones. All in all, the new Quain can be cheerfully recommended to student and practitioner as a complete, practical and readable treatise on anatomy, better than which none exists in the English language.

DES INOCULATIONS PRÉVENTIVES dans les Maladies Virulentes. Par le DR. E. MASSE, avec une planche hors texte. Paris: G. Masson. 1883.

IN this work of ninety-five pages, Dr. Masse gives a history of what has been so far done in attenuating virus and studying its effects. The book is a useful and timely one, although Dr. Masse presents the Pasteur side alone of the subject.

Obituary.

GEORGE MILLER BEARD, A.M., M.D.,

NEW YORK.

THE death of Dr. Geo. M. Beard, which occurred at his home in this city on Tuesday morning, as the result of pleuro-pneumonia, takes from the ranks of the medical profession a bright and shining light. The news of his sudden taking off startled his friends, very few of whom knew that he was even ill. It was only as yesterday that his voice was heard in discussion, that he was met in apparent good health, and was filled with his usual enthusiasm for his life-work. It seems hardly possible that the end should have been so near. Death was, however, not unexpected to him, and toward the last he philosophized upon the rapidly progressive changes of his dying condition, expressing the wish to record the thoughts of a dying man. During his illness he was in his usual cheerfulness, although most of the time suffering great pain. His main concern referred to what he considered his unfinished work, and almost his last words expressed the hope that others might continue it.

Dr. Beard was born at Montville, Conn., and was the youngest of four children. His father, the Rev. S. F. Beard, was a Congregational clergyman. His grandfather was a physician. Dr. Beard prepared for college at Phillips Academy, Andover, Mass. Before entering Yale College in 1858 he spent two years in teaching. He was graduated from college in 1862. He then studied for one year in the Medical Department of Yale College, and in 1866 was graduated from the College of Physicians and Surgeons in this city. Dr. Beard at once settled down in this city, and, with Dr. A. D. Rockwell,

made electro-therapeutics and nervous diseases his specialty. Dr. Beard was a voluminous writer, his first literary attempt being a paper on "Electricity as a Tonic," written in 1866. From that time to the day of his death he wrote constantly, adding many works of singular merit to medical literature. Among his most important works were "Our Home Physician," published in 1869; two popular treatises entitled respectively "Eating and Drinking," and "Stimulants and Narcotics," 1871; "Medical and Surgical Electricity," 1875, with Dr. A. D. Rockwell; "Hay Fever; or, Summer Catarrh," 1876; in 1877, a monograph on "The Scientific Bases of Delusions, Being a New Theory of Trance and Its Bearing on Human Testimony;" in 1880, a practical treatise on "Nervous Exhaustion;" in 1881, a work on sea-sickness, and in the same year "American Nervousness, with Its Causes and Consequences;" in 1882, "Psychology of the Salem Witchcraft Excitement and Its Practical Application to Events of Our Times." Among his later writings were a work on "Sexual Neurasthenia," "The Physiology of Mind-reading," and a host of pamphlets relating to electrology, neurology, and psychology. He also made constant contributions to the *North American Review*, the *Popular Science Monthly*, and *THE MEDICAL RECORD*.

In 1863 and 1864, during a period of eighteen months, Dr. Beard was Acting Assistant Surgeon in the West Gulf squadron of the United States Navy, and in 1868 became a lecturer on nervous diseases in the University of New York. From 1873 to 1876 he was physician to the Demilt Dispensary in the department of electro-therapeutics and nervous diseases. Dr. Beard was also one of the originators of the National Association for the Protection of the Insane, and was a founder of the New York Neurological Society. He was a Fellow of the New York Academy of Medicine, a member of the County Medical Society, the New York Medico-Legal Society, the American Neurological Association, the American Academy of Medicine, and of the American Association for the Cure of Inebriates.

He paid several visits to Europe and made there the acquaintance of many European authorities in science. He was several times a delegate to foreign scientific associations, presented papers to the British Medical Association, and in 1881, was a delegate to the International Medical Congress in London. He was connected professionally, as an expert, with the trials of Guiteau and Cadet Whittaker.

In the Whittaker case he testified for the defence, taking the position that Whittaker, when found with his ears cut, was really unconscious, and that the unconsciousness was the result of fright which came from the attack during the night. Dr. Beard's position in the Guiteau case was that the assassin was insane; that the insanity was of a hopeless and incurable character—religious monomania—and that Guiteau was irresponsible absolutely for the deed. This ground he took in an article in the *North American Review*, but when he was going on the stand to testify to that effect his testimony was ruled out on a legal technicality. He was also instrumental in preparing the petition for a stay of proceedings just before the hanging of the assassin.

Dr. Beard's writings have been especially influential in Germany, and his most important works have been translated into the German language. All his works have been original contributions upon the subjects of which they treat.

No man made for himself so enviable a reputation in his profession by more honest work than did the subject of our sketch. Few who did not know his habits could understand how he accomplished so much. But he was constantly and contentedly busy wherever he might be. He never allowed himself, however, to feel the strain of work. His elastic spirit and calm philosophy always served him in good stead, even upon his death-bed.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, January 18, 1883.

R. F. WEIR, M.D., VICE-PRESIDENT, IN THE CHAIR.

DR. CHARLES MILNE presented to the Academy a beautiful engraving of John Hunter, a copy of the original portrait painted by Sir Joshua Reynolds. On motion of Dr. John G. Adams, the thanks of the Academy were extended to the donor.

DR. PAUL F. MUNDÉ then read a paper on

SECONDARY PUERPERAL HEMORRHAGE.

The majority of obstetric authorities scarcely referred to the possibility that alarming uterine hemorrhage might occur as late as several weeks after confinement, and only the standard works of Barker, Winckel, Playfair, Spiegelberg, and Barnes devoted a fair amount of space to this accident. In September, 1880, at the annual meeting of the American Gynecological Society, Dr. Theophilus Parvin read an elaborate essay on this subject. The fact that so little had been written concerning it, and also the fact that the accident was comparatively rare and grave, were sufficient reasons for reporting the following case, which presented certain peculiarities not referred to by Dr. Parvin.

On August 2, 1882, he saw, in consultation with Dr. S. Kohn, a patient who was in great danger from uterine hemorrhage. She was twenty-five years of age, the mother of three children, and had always been healthy. She was taken in labor on July 16th, with her fourth child. Labor progressed slowly, and after it had lasted twenty-one hours, the head almost resting upon the perineum, and no advance being made, an attempt made to deliver with the forceps failed. The cranium was then opened and the forceps again used, but they refused to hold. The head was then delivered with the cephalotribe. The cause of the difficulty was hydrocephalus. Hemorrhage was quite profuse, but soon ceased. The placenta was adherent to the right side of the fundus and required complete separation by the hand, special care being taken not to leave any fragments behind. Two fluid drachms of ergot were administered by the mouth and all hemorrhage ceased. On examination it was found that the anterior lip of the cervix was quite badly torn. The patient appeared to be doing well for the next six days, although the temperature varied from 101° to 102° F., and the pulse averaged 120. The lochia were fetid from the third day on. Uterine injections washed away numerous small shreds and coaguli until the lochia lost their offensive odor. On July 28th, the lochia again became offensive, the discharge diminished in quantity, was serous, and contained a reddish-black fluid. On the sixteenth day after labor, a profuse hemorrhage began, and when Dr. K— saw the patient, four hours and a half afterward, she was almost exsanguinated. The bleeding was arrested for a moment by intra-uterine injections of hot water, but it soon recommenced. It was again checked by injections of hot water and tamponading the vagina. When Dr. Mundé saw the patient he found her with low head, perfectly pallid face, hands, and feet cold and clammy, pulse 120, very weak, and consciousness unimpaired. The fundus of the uterus was on a level with the umbilicus, irregular in outline, the right horn extending several inches above the navel, and there was moderate tenderness. After preparing fresh carbolized tampons, procuring a few ounces of the pure tincture of iodine, and a fountain syringe filled with hot carbolized water, he rapidly removed the tampons, and at once passed his hand into the dilated vagina and through it into the distended uterine cavity, which he found filled with soft coaguli, exceedingly offensive, dark colored, and largely mixed with shreds of decidua. The

internal surface of the uterus was soft, pulpy, and the mucous membrane apparently very much thickened. Great caution was necessary, in order to avoid injuring, perhaps perforating, the pulpy wall of the organ. After emptying the uterine cavity, he introduced a long metallic tube, and washed it out with carbolized water from the fountain syringe, the water being as hot as the hand could bear. The patient did not complain of the heat. He then introduced a large cylindrical speculum, through the tube of a long cervical syringe, and then injected half an ounce of pure tincture of iodine into the uterine cavity, using some force in order to insure the thorough distribution of the iodine. Cotton tampons joined with a cord were again applied, merely as a safeguard against further hemorrhage, in case the iodine failed to check it, and he directed that they be removed in six hours. The injection of iodine gave no pain whatever, nor was it followed by shock. Six hypodermics of brandy were given, and ten drops of aromatic spirits of ammonia, five drops of spirits of camphor, and a teaspoonful of brandy were ordered in ice water every half hour. A hypodermic syringe full of Squibb's fluid extract of ergot was injected into the subcutaneous cellular tissue of the abdomen, and an ice-bag was placed over the uterus. A bottle of hot water was placed at the feet. Directions were left to inject the uterine cavity very gently with tepid carbolized water after removing the tampons, for the purpose of preventing the decomposition of the coaguli produced by the iodine.

On visiting her twenty-four hours later he learned that no further hemorrhage had occurred, and that the uterus had been washed out several times. There was hectic flush and a peculiar sweetish odor about the patient, which sustained the conviction already expressed, that the patient was suffering from septic endometritis. Tepid injections of a one-sixth per cent. solution of permanganate of potash were made into the uterus every three hours, more or less, according to the offensiveness of the discharge. Ten grains of salicylate of soda were to be administered every two hours, in case the temperature should rise above 102° F., and the stomach did not reject it. Stimulants as might be required. Nutritious enemata. Prognosis unfavorable. In the course of the subsequent treatment, intra-uterine injections of the sulphate of quinine [sulphate of quinine, one drachm to the quart of water] were used at the suggestion of Dr. Kohn, and apparently with marked benefit. The offensive lochia continued several weeks after the hemorrhage. The patient recovered slowly, and at the end of five weeks convalescence was complete.

Dr. Mundé then reviewed several points of interest in the case reported.

First.—The causes of secondary puerperal hemorrhage. Constitutional: hemophilia, mental emotion, functional disease of the liver, incautious use of stimulants, sudden assumption of the erect position. Local: irregular and inefficient contraction of the uterus, clots in the uterine cavity, portions of retained placenta or membranes, retroflexion of the uterus, laceration of the vagina or vulva, laceration or erosion of the cervix, inflammatory ulceration of the cervix, malignant disease of the cervix, pelvic cellulitis, inversion of the uterus, premature sexual intercourse, loaded rectum. To these he added distended urinary bladder. Besides these malarial poisoning was a well-recognized cause of secondary puerperal hemorrhage. General febrile disturbances were also causes of secondary metrorrhagia. Another cause, so far as he had been able to learn spoken of by Winckel only, was disease of the inner surface of the uterus, chiefly endometritis. Dr. Mundé believed that his case belonged to this class.

Second.—The date of hemorrhage after delivery. The time at which secondary hemorrhage is liable to occur varies greatly, according to the character of the labor, the care taken in the third stage, precautions employed during childbed, and accidental circumstances. Barker

refers to instances as late as the fifth or sixth week after delivery, and Helfer speaks of one during the fourth week.

Third.—The significance of secondary hemorrhage depends partly on the amount of blood lost and escaping, and partly on the origin of the blood. Hemorrhage depending on mere temporary atony of the uterus is less serious than if due to sloughing off of the placenta, uterine thrombi, or the bursting of a dilated vein. The occurrence of serious or fatal hemorrhage at a later date than the fourteenth day after delivery was certainly very rare. The evil consequences of protracted secondary hemorrhage were the debilitating effect upon the woman, and subsequent uterine disease of some form or other.

Fourth.—The means employed to check hemorrhage. He recommends the method of injecting iodine through a cylindrical speculum, as a means of saving the vagina and vulva from inevitable contact with the fluid if the latter is simply injected into the uterus under the guidance of the finger. With reference to the application of the tampon after labor, it need scarcely be said that it should never be done unless the uterus was so contracted and constantly watched that no internal hemorrhage could take place. He applied the tampon temporarily as a possible safeguard against external hemorrhage until the patient had had time to rally a little, and with the positive understanding that the fundus uteri should be carefully watched until the tampon was removed. As a rule, it might be assumed that the same remedies and measures which are used to check primary uterine hemorrhage will be effectual in the secondary variety. For a protracted bloody lochial discharge, or a constant sanguineous oozing due to subinvolution, he had, in a number of instances, used successfully the pure tincture of iodine applied to the uterine cavity, about twice a week, on cotton-wrapped applicators.

DR. MUNDÉ concluded his paper by making reference to the means of preventing these hemorrhages, primary and secondary. The following rules were given for the management of the third stage of labor and the early puerperal state:

1. Always keep the hand on the fundus uteri from the moment the head appears at the vulva until the placenta is expelled.

2. Do not hasten the expulsion of the placenta too much.

3. Always watch the uterus with the hand, using gentle friction occasionally, for at least one hour.

4. Always give ergot by the mouth immediately after the birth of the child. If chloroform has been given, or if the labor has been unusually tedious, give ergot hypodermically, injecting a syringe full of the fluid extract to the depth of one inch near the umbilicus.

5. If the uterus shows a reluctance to remain contracted, rub the fundus gently with a piece of ice, or insert a cone-shaped piece into the cavity.

6. Always make sure by palpation and percussion that the uterus contains no coaguli.

7. Apply the child to the breast early.

8. Apply an equably tight binder, and, if there be tendency to hemorrhage, a pad should be placed over the fundus to secure its steady compression.

9. If there be laceration of the cervix or vagina, future oozing may be checked by mild astringent injections, or, if need be, by applications through the speculum. Immediate suture for laceration of the cervix appeared to him to be rarely feasible.

10. Do not allow the lying-in woman to leave her bed before the tenth day.

11. See that the bladder is empty, and is not interfering with uterine contraction.

12. See that the nozzle of the syringe is not introduced too far, and that too much force is not used in giving the customary cleansing injection.

DR. W. M. POLK, on invitation, opened the discussion, and said that he had seen but one case of secondary

puerperal hemorrhage, meaning thereby hemorrhage sufficiently profuse to produce marked exhaustion in the course of twenty-four hours, and in that instance it occurred fifteen days after confinement. He applied a tampon because the uterus was firmly contracted, not large, and besides he watched the organ very closely. He had a misfortune with it, which he believed was worthy of being borne in mind. The tampon was wet with a solution of persulphate of iron in water, three parts of water and one of the liquid preparation of the iron. It remained in position about twelve hours, and after its removal he instructed the nurse to thoroughly syringe the vagina, but she neglected to do so, and the consequence was complete atresia of the vagina, which required a secondary operation for its relief. Dr. Polk also referred to a second case which occurred in the practice of one of his friends, in which the hemorrhage occurred on the fifth day after confinement, and followed an intra-uterine antiseptic injection given through an ordinary catheter. In that case hemorrhage was so profuse that death took place almost immediately. He thought that the possibility of the occurrence of this accident should always be borne in mind in the usual habit of washing out the uterus with antiseptic solutions after confinement. Dr. Polk believed that the causes of this form of hemorrhage could be arranged under two heads: first, local; second, constitutional. His rule has been, whenever he had to deal even with milder degrees of septic inflammation of the endometrium, to be closely upon his guard against the occurrence of this accident. The tendency to improper contractions of the uterus in consequence of septic disease, and a failure to establish proper organization of the clot for the complete closure of the vessels, renders very trivial causes sufficient to produce hemorrhage. The conditions likely to interfere with the proper organization of the coaguli in the ends of the uterine sinuses are, unfortunately, very numerous. In the first place, all septic inflammations belonging to the uterus in the parturient state exert a marked influence in this direction. The other causes were chiefly constitutional, and were summed up under the head of cachectic states, such as malarial poisoning, or poisoning from any of the minerals, as mercury, lead, etc. He did not approve of the practice which formerly prevailed, of forcing the uterus back into the hollow of the sacrum by means of heavy compresses and bandages, for the reason that such mechanical pressure gave rise to congestion of the organ, and was liable, sooner or later, to be followed by hemorrhage. Dr. Polk also preferred hot water to cold. He had seen a good deal of prostration produced after prolonged use of cold, and he had not seen any ill effects follow the use of hot water. Water into which the hand could be placed and retained was not too hot for the uterus, and he thought this was a sufficient test for the temperature of the water. So far as immediate operations upon the cervix were concerned, he agreed with the author of the paper, that they were out of place. He thought the observations made by Dr. C. C. Lee had proved conclusively the correctness of this conclusion.

DR. E. L. PARTRIDGE directed attention to some of the less severe cases than those which had been mentioned by Dr. Mundé and Dr. Polk. He thought that only one-half of the question had been stated when it was said that secondary hemorrhage was due to retention of clots and portions of the secundines, etc., and that the real question was, What is the condition that allows this improper uterine contraction? He then proceeded to speak of the predisposing causes, both local and constitutional, which might give rise to secondary uterine hemorrhage. For example, a woman who suffered from such symptoms as would naturally be attributed to disorders of the circulation, such as headaches due to anemia, attacks of syncope, etc., would be liable to the occurrence of hemorrhage after labor. With regard to local predisposing causes, he mentioned chronic uterine diseases of various kinds, chronic cellulitis which led to an increase in the

size of the organ due to the preponderance of fibrous structure which was liable to interfere with perfect contraction of the organ at the termination of labor. The only alarming case of secondary puerperal hemorrhage which he had seen occurred on the ninth day after labor. It occurred suddenly, and was found to be the result of an annular slough which involved the entire vaginal end of the cervix. The loss of blood was sufficiently profuse to seriously jeopardize the patient's life. The history of the labor was that of early rupture of the membranes. And with regard to early rupture of the membranes, he had found that the persistence of the hemorrhagic element in the lochial discharge was very likely to exist, and it might be sufficient afterward to produce what might be called hemorrhage. In such a case as that reported by Dr. Mundé he would not hesitate to use a tampon, but, generally speaking, he would not hasten to apply a tampon until he was convinced that all other methods for controlling the hemorrhage were futile, because he thought there was a liability to the absorption of septic material. Dr. Partridge then made special reference to the importance of compressing the uterus for some time after the completion of labor, and for the purpose of preventing the occurrence of secondary hemorrhage.

DR. H. T. HANKS concurred in nearly all the statements made by Dr. Mundé, and made reference to cases of undoubted malarial origin which had come under his observation. In one the hemorrhage occurred fourteen days after delivery. It was controlled by the use of a battery and injections of hot water. He agreed with Dr. Polk that hot water was the more easily obtained, and more agreeable to the patient, and more effectual than cold. It could be easily injected through Chamberlain's long glass tube, or a small gum elastic catheter. He did not approve of the use of the tampon. He also thought it unnecessary to give a drachm of ergot in all cases of labor. If there was any evidence of impending danger, certainly the ergot should be used, but if the patient was all right, why give something which produced uterine colic?

DR. MUNDE, in closing the discussion, said he did not concur with Dr. Polk with regard to the effect produced by the binder and pad. He thought their use was simply the application of the same principle which was so frequently applied for the arrest of hemorrhage in any other part of the body. With regard to the use of heat or ice, he did not wish to be understood that he would use ice-water, but he would simply take a piece of ice and rub it over the fundus, or introduce a piece into the cavity of the uterus. It had been his experience that the patient complained more with regard to the use of hot water than the use of cold. Dr. Partridge's remarks were exceedingly proper with regard to the etiology of hemorrhage in certain cases, but it had not been his purpose to enter upon the subject of the etiology of uterine hemorrhages, which were of a more chronic character. He wished to speak chiefly of the acute cases. The subject of protracted lochial oozing he thought had not been sufficiently elaborated. He believed that the condition was exceedingly common, and that a great deal could be done in the way of its prevention and cure. With regard to the use of the tampon, he did not wish to be understood as recommending its introduction after delivery of a full-grown child. It certainly was a risky practice, but in his case he preferred to take the risk rather than to allow the patient to lose another drop of blood. But it should be insisted upon that it be very carefully watched. He did not believe that it was always necessary to use ergot after delivery, but at the same time he thought the woman was a little more safe with than without it, and he did not believe that it did any harm.

DR. POLK remarked that he did not mean to criticize the application of the binder and compress, but simply wished to speak of the custom of continuing it for a week or ten days after labor.

DR. E. B. BRONSON then read a paper on

ECZEMA: THE PATHOLOGY AND THE PRINCIPLES OF ITS TREATMENT.

He believed that the epidermis played a part in the pathology no less essential than the vascular stratum beneath it, and that it was primarily involved. He also maintained that there was an independent action on the part of the epidermal cells in the inflammatory condition of eczema. The adjacent vascular tissues, however, soon sympathized. Dr. Bronson then spoke of the conditions which favored the view advanced, and mentioned the fact, recently demonstrated, that the epidermis as well as the papillary layer is supplied with nerves. Eczema manifests itself in sensory disturbances and in trophic changes in the epidermis. The trophic change is under the influence of the epidermic nerves, and the itching was probably due to their disorder. Of the pathological anatomy of the epidermic nerves in eczema, but little was known. Dr. Bronson then presented at some length the reasons which had led him to the adoption of this new theory concerning the pathology and etiology of eczema.

The therapeutic indications were, to allay irritation and assist repair. Measures of rest and measures of stimulation comprised the whole method of treatment of eczema. The local agents were embraced under mechanical, chemical, and dynamical. The highest grades of eczema were usually treated best by wet applications. Lotions might hold in suspension powders or certain chemical materials, such as moderate astringents or alkalies. Sometimes it was of advantage to use a certain proportion of glycerine in the lotion. Undiluted glycerine acted as an irritant. Wet applications to be most effectual must be continuous and copious. A little later emulsions might be used, and a little later still the period for the use of ointments had arrived. Of the ointments the zinc was the best that could be employed where a protective ointment was indicated. The use of ointments was contra-indicated in the early stages, and there were other circumstances under which they were contra-indicated, such, for example, as the existence of more or less erosion with copious discharge, when the use of absorbent cotton or an absorbent lotion was more serviceable.

The next class of agents considered was those which modified vital action, and chief among these were the alkalies, which produced a sedative influence over the sensory nerves. They were most effective when the nervous layer of the epidermis was exposed. In old cases of eczema the stronger potash soaps were indicated, but in the milder cases the milder soaps acted most favorably. In squamous eczema the soap treatment was the most effectual which could be employed. It was seldom that a stronger alkali than soft soap was required. Hot water for the relief of the pruritus of eczema was very serviceable. It should be used to the extent of substituting a sense of smarting for that of itching which would be succeeded by a sedative effect. To insure a continuous effect of hot water, it should not be stopped too soon. Dr. Bronson then spoke of the indications for the use of carbolic acid, preparations of tar, etc. In the stage of active exudation the use of tar was contra-indicated. Among the remedies belonging to this class was the benzoated oxide of zinc ointment. Mercurials were indicated chiefly in the later stage, when the skin was no longer in a state of active inflammation, but was suffering in nutrition from the accumulation of the products of inflammation. In these cases mercury was most efficient.

When is it necessary to resort to internal medication? Dr. Bronson considered this question at some length, and believed that internal medication might be of some service in diminishing reflex irritation, in restoring the general tone of the system, and in aiding local remedies. He thought it quite possible that eczema resulted most frequently from the combined effects of an irritation

from within and another from without. After presenting the views entertained by the French School of Dermatologists, Dr. Bronson reached the conclusion that whatever the predisposing causes might be, eczema in the main was essentially a local disease, and the most rational treatment that could be adopted was directed to the skin itself. Internal remedies were subordinate to local measures. The use of narcotics should be mentioned only to be condemned. In the majority of cases the local treatment was able to cope with the disease.

DR. R. W. TAYLOR, being invited to open the discussion, said that he had listened with great interest to the paper read by Dr. Bronson, although it had a theoretical flavor which perhaps was not so sound as its practical character. With reference to the pathology of the affection, he thought Dr. Bronson had been rather too superficial, believing that the disease has its beginning above the rete mucosum. Eczema being a chronic disease, and involving the entire skin, Dr. Taylor thought that if Dr. Bronson had included the deeper invasion of the disease in his description, it would have added much to the completeness of his paper. That the disease commenced in the vascular layer of the skin and extended above and below, he thought would be conceded by all those who saw much of eczema.

With reference to treatment, it could be formulated something as follows: In the erythematous stages soothing applications, either in the form of powders or lotions, such as lead and opium, were most serviceable. As the disease increased in age, stimulation should be added. He believed that stimulation was one of the cardinal points in the treatment of eczema, keeping the surface well protected, and then going on gradually with the use of stimulating applications. The application of the zinc ointment alone would not effect a cure, unless something was added, and then the use of tar came in most admirably. Dr. Taylor believed that in most cases, treatment with the use of alkalies could be extended further than had been mentioned by Dr. Bronson, and that strong solutions of potash might be used with advantage. Soaps would fail in some cases where solutions of potash would relieve, even of the strength of a drachm of the caustic potash to the ounce of water. The action of this strong solution must be controlled so as to get the effect of strong stimulation and at the same time prevent it from producing inflammation. With regard to the nature of the disease, he was glad to hear that Dr. Bronson discarded the rheumatic and dartrous diatheses which were so completely visionary. There was one fact to which he wished to direct especial attention, and which had not been dwelt upon by the author of the paper. A patient has eczema, and has had it for a long time. If you go back into the history of the case, you generally find that he has had a local eczema more or less severe; in other words, while young he suffered from attacks of inflammation of the skin, which has rendered it more vulnerable all through life than it otherwise would have been. The more frequent the occurrence of these attacks of inflammation of the skin in early life, the more the patient is predisposed in later life to eczema, simply from the bad habit which the skin has taken on in former days. Dr. Taylor also thought that arsenic had not been sufficiently recommended. He believed that it would assist the external treatment very much. The golden rule in the treatment of eczema was to use local measures, but in many cases the internal use of arsenic would be found very beneficial.

DR. BULKLEY regarded Dr. Bronson's paper as one of the best expositions of the idea of eczema which had ever been presented. With regard to the conditions, the stages and the treatment for each, if what had been said could be properly studied, it would help all in the management of the affection. The subject of the alterations in the cellular layers of the skin were necessarily important, and had not received the attention which they should have done in years gone by. That the skin

should take on this particular action, and the patient become the subject of such a tendency which might last through a life-time, was undoubted. The bearing of the nervous system in the disease he thought was important to be borne in mind, and was an important factor in studying the etiology of the affection. Dr. Bulkley, however, held that in the vast majority of instances the skin would not take on the eczematous action when the individual was in perfect health. A person who suffered from eczema in any degree, and in whom the process has lasted for any considerable time, was not in perfect health. There was no specific for eczema, and yet he had reported several cases in which he had given nothing except Fowler's solution internally, and the cases were relieved at once. He believed that in nine out of ten cases of eczema arsenic should be administered internally at some time in the course of the disease.

DR. TAYLOR asked Dr. Bulkley what he meant by the term, "is not in perfect health;" in other words, whether or not he believed there was a herpetic or dartrous, or some other diathesis which produced the disease?

DR. BULKLEY replied that he did not believe in a herpetic or dartrous diathesis, nor did he believe in an eczematous diathesis, but referred to the debilitated condition of the patients, and to the fact that some other organ besides the skin is in an abnormal condition.

DR. TAYLOR asked, how explain the cases of eczema which occur in patients in whom there cannot be found any deviation from health?

The Academy then adjourned.

SECTION IN PRACTICE.

Stated Meeting, January 16, 1883.

E. G. JANEWAY, M.D., CHAIRMAN.

ABSCESS OF THE LIVER—ABSENCE OF HYPOCHONDRIASIS.

THE CHAIRMAN reported a case of abscess of the liver in which there was no evidence of hypochondriasis. In a number of cases of hepatic abscess he had noticed the absence of hypochondriasis, and had come to regard its presence as exceptional instead of the rule.

EYE TROUBLES ERRONEOUSLY ATTRIBUTED TO LESION OF THE BRAIN AND NERVOUS SYSTEM.

DR. H. D. NOYES read a paper on the above subject in which he directed attention first to a class of cases in which the *objective* observations might be faulty; and second, to a considerable class of cases in which functional disturbances were sometimes regarded as significant of trouble in the nervous system, whereas in truth they originated in the eye.

What he had to say was not by any means to be interpreted as disparaging to the ophthalmoscope, but rather to encourage a more general use of the instrument than had heretofore obtained in both hospital and private practice.

The connection between diseases of the eye and the nervous system especially had come to be very thoroughly appreciated, and the more so since the ophthalmoscope had proved itself an instrument capable of giving so much valuable information bearing upon the latter class of affections.

There were, however, certain objective facts observed in the eye by the aid of the ophthalmoscope that were capable of misinterpretation. First, the optic nerve varied, to a degree not properly appreciated, in the color which it presented on ophthalmoscopic examination. It varied so much that an inference drawn from its undue vascularity with reference to the possibility of trouble with the circulation in the brain was liable to lead to erroneous conclusions. Acute affections of the brain rarely exhibited themselves in hyperemia of the optic nerve. When they did the disease was at the base of the brain, and was meningitis, disturbances associated with fracture, abscess, etc. Acute inflammation of cere-

bral tissue rarely exhibited itself in lesions which could be seen in the optic nerve. Most of the brain affections, evidences of which manifest themselves in the optic nerve, were chronic in character, such as interstitial changes, new growths, etc.

An intensely reddened optic nerve must be accompanied by other symptoms before assuming that it was associated with lesion of the brain. It was more frequently the result of strain or irritation of the eye or of congenital defect than of disease of remote tissues.

Choked disk had an important bearing upon the diagnosis of tumor of the brain, and yet there might exist swelling and infiltration of the optic nerve without any evidence whatever of brain lesion, nor could it be assumed that the case was one of latent tumor of the brain. These cases were not of common occurrence, but had occasionally been observed. The appearance of the retina varied considerably in different persons. In young subjects it was frequently seen as a glistening somewhat opaque reflection and especially noticeable were long blood-vessels. This condition, due to the brilliant reflection of the light, in no respect indicated that the retina was the seat of inflammatory infiltration, and should not be mistaken for evidence of an inflammatory process.

The general illumination of the fundus of the eye varied greatly in different subjects, according to the size and complexion of the person, etc. Besides, there was frequently seen along the edge of the optic nerve a bright, opaque, striated surface, running out from the nerve itself and swelling its edge, that might be mistaken for exudation. It was a bundle of imperfectly developed nerve fibres; was a congenital condition, and had no influence, either local or general. On the other hand, the optic nerve was sometimes very pale, and the blood-vessels small; but pallor and reduction in size of the blood-vessels did not necessarily indicate atrophy. It was sometimes evidence of general poverty of the circulation, but existed entirely distinct from any alteration of the nerve fibres proper.

Dr. Noyes then referred to a case in which an experienced foreign oculist saw an appearance in the eye which he regarded as evidence of inflammation, and from this and other symptoms he was led to the conclusion that there was intra-cranial disease. The real condition, as subsequently proved beyond doubt, was a notable error of refraction in one eye, which had not been used until disease in the opposite eye rendered its use necessary. The subjective phenomena liable to be mistaken for evidence of disease of the brain were chiefly due to errors of refraction, as hypermetropia, astigmatism, spasm of accommodation, and trouble with the extrinsic muscles of the eye. This was by no means a new subject. It was Weir Mitchell, of Philadelphia, who, perhaps, had attached most importance to it as a field in which causes of peculiar nervous symptoms could be found. The class of cases which Dr. Noyes mentioned were those in which the patients made comparatively little or no complaint whatever with reference to the eye.

The first and chief symptom which develops in these cases was *headache*; and it could be of any possible variety, as frontal, occipital, pain in the temples, vertex, etc. It might occur upon one side only, although such cases were comparatively rare.

This headache might or might not be associated with special use of the eyes. Sometimes it appeared on first waking in the morning. It might be increased by any mental labor. It was not infrequently attended by nausea. The headache was liable to be exceedingly persistent. In a case, in which headache is the chief symptom complained of, an examination of the eye might reveal deep congestion of one optic nerve, a degree of congestion, associated with marked opacity, in the other; and the observer might be easily led, perhaps, to think that it was a case of some chronic meningeal trouble. Yet all this might be due to hypermetropia, and the same

symptoms might also make their appearance without refractive error.

Dr. Noyes then referred to a case in which a large part of apparent mental and cerebral disturbances was due to intense spasm of accommodation. The patient appeared to be near-sighted and required concave glasses, No. 12; but examination determined entire absence of refractive error, and that the condition was apparent and not real. Atropia was freely and vigorously used, and although marked relief had been obtained the spasm had not entirely relaxed. The cause of the spasm was probably in concussion of the spine, but the principal symptom had taken possession of the patient, and the conclusion had been reached that the trouble was in the eye alone.

The speaker then gave the history of a case of disordered condition of the muscular apparatus of the eye. A young woman was near-sighted and also had divergent strabismus. A great variety of nervous phenomena attended the case. She had been advised not to have an operation performed for the squint. From repeated examinations, Dr. Noyes became convinced that the symptoms were due to the condition of the eye, and recommended an operation for the relief of the divergent strabismus, and the result was extremely satisfactory; not only was the pain relieved, but the general health of the patient materially improved.

The subject of irritation produced by disturbances of the ocular muscles was one which had been agitated considerably among ophthalmic surgeons, and concerning it there was not an unanimity of opinion. There was a variety of opinions with regard to the possibility of nervous disturbances being developed by disorders of the ocular muscles, but the differences were rather based upon the degree of influence which these disorders exert; and while there were exaggerated views which altogether failed of being confirmed by experience, he was persuaded that these ocular disturbances exerted a far greater influence, not only upon the functions of the eye, but upon the general health of the patient, than was, for the most part, allowed to them.

As an illustration of how certain symptoms, dependent upon this condition, were expressed by patients, he gave the history of a case in which the patient, a girl fourteen years of age, described the symptoms from which she suffered. In this case there was only extreme debility of the internal recti muscles. The patient had suffered from headache for three years, worse latterly, people seemed to be moving away from her when she looked at them, she was unable to look fixedly upon objects, inability to ride in the cars, etc.

How are the cases to be differentiated and some of the errors avoided? To properly study the objective phenomena requires sufficient knowledge to enable the observer to say what was normal and what abnormal. In using the ophthalmoscope, the *direct* method was the most valuable, that mode in which the instrument was supplied with glasses to correct optical errors, as by it the observer was able to determine whether he was dealing with a normal or abnormal eye, so far as refraction was concerned. In addition, the quality of vision must be examined with test-types and correcting glasses. Finally, under suitable circumstances, resort might be had to atropia. If this drug was used, it was well to notify the patient that no ultimate detrimental influence would follow. It was not necessary to use atropia where there was reason to believe that serious brain trouble existed, but where the nervous manifestations were subjective in character, such as headache, nausea, inability to fix the eyes upon any object, and no well-defined evidence of brain trouble, atropia might not only clear up the diagnosis, but might relieve the symptoms. It frequently removed headache, although temporarily, permanent relief coming from wearing glasses. The difficult refractive cases were those in which there was also astigmatism.

The severity of the symptoms in these cases depended very much upon the temperament of the patient; some suffering severely, others only slightly, from the same condition of the eyes. Those who suffered from uterine troubles were especially liable to suffer from various reflex irritations, and disturbances of the eyes were not exceptional.

For muscular errors the *treatment* consists in rest, the use of suitable prismatic glasses, sometimes tenotomy, and proper attention to all general causes and remote lesions which might have an influence in producing such disorders. Muscular and refractive errors were sometimes combined, and sometimes so combined as to make the prescribing for glasses exceedingly complicated.

DR. WEBSTER thought that Dr. Noyes had not made a single statement to which any member of the New York Ophthalmological Society would take any particular exception, thus presenting a striking contrast with the neurologists.

DR. PUTNAM-JACOBI referred to certain anatomical considerations which might aid in explaining functional disturbances of the eye from preripheral irritations; and also to the influence in producing muscular troubles exerted by the lack of stability, uncertainty, and impaired equilibrium both on the part of the patients and of anything by which they are surrounded.

DR. BEARD asked Dr. Noyes, first, if he had watched the cases described sufficiently long to enable him to determine whether or not *permanent* relief had been afforded by the means mentioned, not only for the ocular trouble, but for the general nervous system; and, second, how he could tell whether these conditions of the eye were mainly the result or the cause of the disease.

These were suggestions which he had been trying to answer for several years, but had found it impossible to answer them completely in any case. He believed that the subject was a general one; that the whole body was a bundle of reflexes; that the same principles applied just as well to the stomach, the uterus, the prostatic urethra, etc., as to the eyes, and the same problems came up in each instance.

In some cases disease of the womb, the prostatic urethra, the stomach, or of the eye was the very exciting cause of the disturbances of the nervous system, but so far as he had observed the number of cases was very limited. However, if one out of a thousand could be cured by proper attention to the eyes it was a fact of importance, and was sufficient to make us study all our cases in this special direction.

He had not seen cases of nervous disease, functional or organic, where important and permanent results had been obtained by circumcision or operations for stricture. Yet he believed upon authority that such cases existed.

His conclusions were that it was well, in all cases, to find out all we can about the eyes, even if they have already been studied by oculists, perhaps carefully; that the condition of the eyes was simply a help, an occasion in treatment and not the main thing; that, upon authority purely, he believed there are cases where all that is necessary is to treat the eyes, but he had not seen them; that the condition of the eyes was an important one, and he had been interested in determining which was result and which was cause.

There was one important point brought out by Dr. Noyes, and it was that there is a great difference in the capacity of different persons with reference to tolerating hyperæmias and irritations.

DR. LEALE referred to a case in which the patient, fourteen years ago, suffered from nearly all the symptoms mentioned by Dr. Noyes. They were believed to be produced by the condition of the eyes, and glasses eighteen and fourteen were prescribed. Since that time the patient had not suffered from any cerebral disturbances.

DR. PUTZEL thought that, in these cases of muscular troubles referred to, there was a continuous outflow of

nerve-force which must act as a constant strain upon the nervous system, and finally resolve the difficulty into neurasthenia.

DR. BIRDSALL referred to a case in which there was intense headache shortly after reading, and finally maniacal attacks developed. A hypermetropic condition of the eyes was discovered, and for it glasses were worn. The result was marked improvement for a time, but then the headache returned and the maniacal attacks subsequently. The glasses were changed and with partial relief, but recovery did not take place until the boy was removed from school and put upon a farm. The error of refraction was probably the immediate exciting cause of the headache and mania, but it seemed to him that in all such cases a multiplicity of influences were at work, and that the ultimate reference must be to the nervous system. He had seen several cases in which headache had been relieved by correction of errors of refraction with glasses, but believed that the headache and other symptoms would not develop in such cases were the nervous system in a normal condition.

THE CHAIRMAN said that Dr. Beard had alluded to some cases which all would recognize as those in which probably all methods of treatment were hopeless, because of the presence of errors of development of the nervous system beyond the reach of medicine or other curative means.

DR. PUTNAM-JACOBI said that in addition to imperfect development of the nervous system we had to consider that the length of time the nervous centres have suffered from peripheral irritation has permitted considerable change to take place in them, and also that the periodical pain and other disturbances is apt to remain after the peripheral source of irritation has been removed.

DR. WEBSTER had seen many cases of headache in which the patients had been permanently relieved by the use of glasses.

DR. NOYES, in closing the discussion, said that he had endeavored not to attach undue importance to the ocular side of the question, and was able to state that he had a very long list of cases in which the patients had been permanently, positively, and absolutely cured of all their troubles by properly treating the eyes. He could also bring another class of cases in which only partial relief had been obtained. Again, he had another class of cases in which he had been unable to afford the patients any relief whatever by such measures. That the constant pain produced nerve exhaustion he regarded as an important consideration. The habit of pain, also, in some people, seemed to be unconquerable. A good general condition acted favorably upon local conditions, but there were local conditions from which, if not corrected, the patient would always suffer, and, if corrected, the patient would be comfortable.

The Section then adjourned.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, January 22, 1883.

DAVID WEBSTER, M.D., PRESIDENT, IN THE CHAIR.

DR. A. D. ROCKWELL read a paper on

THE DIFFERENTIAL INDICATIONS FOR THE USE OF DYNAMIC AND FRANKLINIC OR STATIC ELECTRICITY.

When a distinguished professor can say to a large class of students that a simple Faradic apparatus will practically answer every purpose in medical electricity, it is in order to discuss this subject. To state that electricity has been used conveys but little meaning unless the *kind* of electricity is mentioned, and, still further, the method of its application. It is not, however, to be supposed that one form of electricity is adapted to one line of disease, a second to another, and a third to still another. But

there are certain pathological conditions which always call for a certain kind of electricity, and if benefit is to follow it must be through this special form, all others being useless, or worse than useless. For example, in hemiplegia, where there exists, as is often the case, an exalted electro-muscular contractility, electricity, if used at all, should be in the form of Faradization, and with an exceedingly mild, rapidly interrupted current. Even when muscular contractions are somewhat less readily called out than in the normal condition, the same current is, as a rule, preferable. On the contrary, when there is very great diminution of electro-muscular contractility, the galvanic current is always indicated, the Faradic coming into play only when the muscles give evidence of positive reaction to its influence.

In most cases of paraplegia, complete or proximate loss of Farado-muscular contractility exists, at least for a short time. The galvanic current alone is applicable in these cases, and for the purpose of restoring nerve-excitability. The Faradic current may be useful in attempting to improve the impaired nutrition of the paralyzed members. When we wish to directly affect the central nervous system, the constant current alone is applicable. In the majority of diseases where electricity is indicated, each one of its forms, Galvanism, Faradism, or Franklinism, may at one time or another possess a positive value over the others. This is illustrated in the treatment of neuralgia. The well-known power of the galvanic current to relieve many forms of pain has been repeatedly emphasized, and the inference has been that Faradism is of but little value for this purpose. The truth is that Faradism is not only invaluable in many forms of pains, but in certain conditions relieves, where Galvanism is not only useless, but may even aggravate the symptoms. The effects of pressure in the various forms of neuralgia, are exceedingly useful, as giving symptoms indicating the proper current. In the great majority of cases of neuralgia, where firm pressure over the affected nerves aggravates the pain, the galvanic current is indicated, whereas, where pressure does not cause an increase of pain, the Faradic current has the greater power of relieving pain. For hysterical hyperæsthesia, the Faradic current is infinitely superior to the Galvanic. Special characteristics of the cases regulate the measure of benefit to be derived from one form or another of electricity, and yet it is impossible to point to many diseases where one current is to be used to the absolute exclusion of the other; but it is possible to name a variety of conditions where, as a rule, one method of treatment and one form of current is superior to another. In the class of cases commonly spoken of as general debility the Faradic current is indicated. It is selected for its tonic effects. Very much, however, depends upon the method of its use. General Faradization is of the first importance. With regard to individual conditions that seem to demand the Faradic current alone there is not much to be said. There are but few distinct organic or functional diseases that in every phase of their manifestation demand alone and always a special form of electricity. Asthenopia, accompanied by hyperæsthesia of the retina and ciliary nerves, is one of the few distinct conditions which seems to demand the Faradic current alone. According to his experience, Galvanism is practically excluded in these cases. The paralysis following diphtheria is another condition for which Galvanism is of but little service.

The author then related the history of several cases. For special irritation or special neuralgia so-called, Galvanism is almost exclusively indicated. Galvanism is specially serviceable in certain sequelæ of cerebro-spinal meningitis, such as severe pain, sometimes beginning in the eyes and extending over the head to the neck and lower cervical vertebrae, associated with a stiffness of the muscles of the neck, etc. Exophthalmic goitre requires Galvanism. For the restoration of the senses of taste and smell, Galvanism succeeds where Faradism fails. Galvanism is superior to Faradism in the treatment of skin affec-

tions. For the relief of the pain of herpes zoster Galvanism is eminently efficacious. Galvanism, according to his experience, was preferable in the treatment of extra-uterine pregnancy. For chorea, if the appetite is good and nutrition unimpaired, and the strength vigorous, central Galvanism was almost invariably indicated; on the contrary, if the patient is weak, anæmic, and nutrition impaired, general Faradization is indicated.

In amenorrhœa the same principle holds good. In dysmenorrhœa both currents, either alone or in alternation, have proven efficacious, although the Galvanic is most frequently indicated. With regard to Franklinic electricity, he should say that while its constitutional tonic effects are unequal to those which follow general Faradization, where this method is carried out properly and with due attention to details, yet as an adjuvant or supplement it was invaluable. Occasional cases of nervous exhaustion, as well as other forms of disease, after improving to a certain point under the influence of Galvanism or Faradism, cease to improve, but a new start can frequently be given by then resorting to Franklinism. Pain is sometimes relieved by Franklinism after both Galvanism and Faradism have failed, but it is not the rule. The pain of muscular rheumatism, however, is relieved by this method sooner and more effectually than by the others. For this purpose the treatment by the roller is superior to treatment by sparks. In the various forms of true neuralgia Franklinism is not comparable in power to Galvanism. The pain so successively relieved by Galvanism is generally of a chronic character confined to no special nerve-trunks, dull aching, and with no tenderness on pressure. In these instances Faradism is superior to galvanism, and recent experience had convinced him that Franklinism was superior to either. In the enlarged joints of sub-acute and chronic rheumatism, and to facilitate absorption in chronic synovitis, Franklinism (sparks) is frequently more efficacious than either Faradism or Galvanism. In old contractures and in cutaneous anæsthesia Franklinism is frequently superior to either of the other forms of electricity. In electro-diagnosis, Franklinism is of but limited value.

Valuable as is Franklinic electricity it has a more limited range of usefulness than dynamic, and the more strongly this fact is impressed on the professional mind the better. He who begins with Franklinism to study and practise medical electricity begins at the wrong end.

The paper being before the Society, Dr. Jacobi was invited to open the discussion, and he remarked that he could add little or nothing to Dr. Rockwell's concise paper, but he would mention one class of cases which would terminate fatally unless the patients were treated energetically and promptly—namely, that in which the patients suffered from paralysis of the respiring muscles in diphtheria. Sometimes this occurs in the course of other paralyzes. But unless it was treated successfully the patients died of apnœa, and a strong Faradic current should be applied and frequently repeated. Electricity used in the usual manner in such cases was of no avail.

DR. L. A. SAYRE said that his daily experience corroborated all that Dr. Rockwell had said.

DR. J. P. GARRISH thought that electricity should not be used in the acute stage of any disease.

DR. ROCKWELL remarked that it should not be used in the acute diseases as a rule.

DR. JACOBI made the broad statement that Galvanism mainly, perhaps exclusively, is used in all affections of the vaso-motor and trophic nerves, and asked Dr. Rockwell if such statement was in accord with his views.

DR. ROCKWELL replied that as a general law it was true, but he doubted the propriety of making it absolute. For instance, facial paralysis due to cold, rheumatismal in character, could hardly be called an affection of the vaso-motor nerves, and yet the Galvanic current was the one best adapted to its treatment. He thought, however, that the law was almost complete.

DR. JACOBI thought that perhaps the exception made by Dr. Rockwell might come under the general law, inasmuch as the rheumatismal character, so-called, of the paralysis might also be the result of disturbances of the circulation.

DR. ROCKWELL thought that to some extent, probably, the paralysis was due to disorder of the circulation; yet his view was that in these cases of facial paralysis the inter-muscular nerves are affected. The Galvanic current acts upon the inter-muscular fibres altogether. The Faradic current produces contractions through these nerves, and these being affected by the rheumatic poison it has no further effect.

DR. JACOBI remarked that these are mild cases; that is, get well speedily, and that that could not be the fact if the nerve substance itself was affected, but it was consistent with the existence of disorder of the circulation.

DR. LEWIS had never seen electricity applied during the acute stage of diphtheria, and thought that more specific directions concerning its application would be beneficial.

DR. MITTENDORF remarked that, according to his experience, paralysis of accommodation following diphtheria had been benefited much more by the use of the Faradic current than by the Galvanic. He had also observed that the pain so frequently suffered from with weak internal recti muscles had been greatly relieved by the use of the Faradic current. He had found, on the other hand, that for amblyopia, due to tobacco or loss of blood, most benefit had been derived from the use of the Galvanic current, probably from the beneficial effect produced upon the blood-vessels, and consequently upon nutrition.

THE PRESIDENT had nothing very favorable to report concerning the use of electricity in ophthalmic practice.

DR. W. M. CHAMBERLAIN had used Faradism in the treatment of facial paralysis with the idea that it was a paralysis which was due to peripheral causes, and that a corresponding action was a legitimate method of retracing the line of causation.

DR. G. W. JACOBY had been governed by the state of nerve degeneration in the use of Galvanism and Faradism. If there was nerve degeneration, according to Erb's rules he used Galvanism; if none, he employed Faradism.

The Society then adjourned.

DR. TANNER'S VAGARIES.—Dr. Tanner, who has been several times reported dead or missing, now turns up again, this time as a victim of connubial revolt. Dr. Tanner has always been addicted to peculiar fancies. Some time since, says the *British Medical Journal*, he thought that he had found out that the human character becomes modified according to the food taken by the individual, and especially in relation to the vegetables consumed. Carrots, he avers, make people fidgety and sly; turnips produce extreme amiability, while a prolonged diet of French beans induces great irritability of temper. The carrying out of this theory has brought great trouble into Dr. Tanner's home. He made a heavy wager on the question with some friends, and experimented on Mrs. Tanner with French beans, giving her to eat about three pounds of this vegetable daily. It is not altogether to be wondered at if, after such a regimen, Mrs. Tanner became rather more irritable than was perhaps contemplated, and threw a jug at Dr. Tanner's head. The doctor, however, gained his bet; and, more thoroughly convinced than ever of the truth of his theory, put his wife on the turnip diet, so as to make her as amiable as she was before the French bean regimen. This time, however, the result was not so strictly in accordance with the theory. Mrs. Tanner objected to be any longer a subject for these vegetarian experiments; sued for a divorce and, what is more singular, obtained it.

Correspondence.

OUR PARIS LETTER.

(From our Special Correspondent.)

FACTS CONCERNING THE LAST ILLNESS OF GAMBETTA—THE NATURE OF THE INJURY TO THE HAND—PERITYPHLITIS WITH DEEP SUPPURATION EVENTUATING IN SEPTICÆMIA—AN ACCOUNT OF THE AUTOPSY.

PARIS, January 5, 1883.

M. GAMBETTA, the news of whose premature death has already spread far and wide, was, about six weeks ago, at his country house, a little out of Paris, wounded in the right hand by a pistol shot, whether accidentally or not, does not concern us as medical men. The bullet entered the palm of the hand, passed along under the skin, and made its exit above the middle of the forearm. There was scarcely any hemorrhage, and the patient did not complain much of pain in the wounded limb. Dr. Lannelongue, as surgeon, and Dr. Sirédey, as physician, who were personal friends of the deceased statesman, were summoned from Paris, and were in immediate attendance. The wounds in the limb healed kindly, and no untoward symptom manifested itself until about a fortnight later, when the illustrious patient was seized with intestinal pains, which did not seem to cause much anxiety in the minds of his medical attendants, as it was considered merely a passing or accidental indisposition. The pains, however, which were at first more general, became concentrated and limited to the right iliac region, and there were other evident symptoms of the commencement of perityphlitis, whereupon Drs. Lannelongue and Sirédey desired a consultation, and Drs. Verneuil and Trélat (surgeons), and Drs. Charcot and Fienzal (physicians), were called to give their opinion on the case. These gentlemen confirmed the diagnosis of the medical attendants, but no active measures seem to have been taken to subdue the progress of the disease. Symptoms of suppuration soon set in, and then it became a question whether an opening should be made to give vent to the matter; but, for some reason or other, operative measures were considered inexpedient, and even dangerous, owing to the obese, and otherwise unhealthy, condition of the patient, who had been for some time suffering from diabetes. The patient gradually grew worse; but whether the medical attendants formed a correct prognosis or not, the bulletins issued were thoroughly misleading; for, within only a few hours of the fatal termination, the public were led to infer that hopes were entertained of his recovery.

The illustrious patient himself was fed with hopes that he would soon recover. Symptoms, however, of a grave nature having set in, he began to feel alarmed, and finding indecision and hesitation written on the faces of his medical attendants, courageously suggested that if an operation were considered advisable, he was ready to submit to it, or to anything that may be necessary for his recovery. This conversation took place on Sunday morning (the day of his death). He was seen again in the afternoon, when his medical attendants still seemed to be ignorant of his real condition. At ten o'clock, however, of the same night, symptoms of the approach of the fatal end became evident, and he expired within five minutes of midnight, from, as was afterward stated, purulent infection.

In this, as in similar cases, the public must conclude, either that the medical men were mistaken or were ignorant of the prognosis, or that they were guilty of wilful deceit. Such a proceeding is inexplicable, and should be altogether condemned. The announcement of M. Gambetta's death, which took place on the night of New Year's eve, was as unexpected as it was appalling, and there was but one sentiment felt, that of universal grief—a sentiment expressed even by his greatest political enemies.

Owing to the unsatisfactory demeanor of the medical attendants in this melancholy affair, and owing also to the sinister reports that were in circulation as to the real cause of death of this eminent statesman, the public demanded that an autopsy should be made and published officially. Accordingly, under the orders of the judicial authorities, the following gentlemen proceeded to the country residence of M. Gambetta: Drs. Charcot, Lannelongue, Cornil, Fienzal, Sirédey, Trélat, Brouardel, and Mathias Duval. The necropsy was undertaken by Professor Brouardel, medical legist, who was assisted by Professor Cornil, and Dr. Lannelongue drew up the report according as it was dictated by Professor Brouardel, and in presence of the medical men named, and other political and personal friends of the deceased. The following is an extract copy of the report:

"VILLE D'AVRAY, January 2, 1883. (11 A.M.)

"1. Traces of old inflammation, causing stricture of the junction of the small intestines and the ileo-cæcal valve.

"2. Extensive and deep extravasation of pus behind the colon and in the abdominal parietes.

"3. A slight degree of peritonitis generalized, which was produced only a very short time before death. The other organs presented no lesion whatever. The wound in the hand was completely healed."

The report concludes with the assertion that death was caused by perityphlitis and suppurative pericolicitis, and that surgical interference was not only inadvisable but dangerous. The latter could have had no other result than shorten the life of the patient. This report was signed by Professors Paul Bert, Brouardel, Charcot, Cornil, Trélat, Verneuil. Drs. Lannelongue, Sirédey, Fienzal, Liouville, Mathias Duval, Laborde, Guerdat, Gille, and M. Paul Gibier, Interne in attendance. It should be mentioned that to Professor Mathias Duval, so well known for his researches on the anatomy of the brain, was confided the examination of that important organ. The brain in this case weighed 1,100 grammes.¹ Nothing else was particularly noticed in that organ. In fact, a more detailed report will be ultimately published. The next day the body of the illustrious defunct statesman was removed to the Bourbon Palace in Paris (the official residence of the Minister of Foreign Affairs), where it now lies in state until to-morrow, when the funeral will take place, with all the honors paid to the Chief of the State, which, had his life been spared, he would sooner or later have become.

COURTESY IN MEDICAL DISCUSSIONS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: The object of this letter is peace. The results of partisanship in this country are sometimes of a character not to be desired. This we all know. The medical profession in the State of New York at the present time cannot be regarded as "a house divided against itself." We are only sharply at variance on one minor and almost incidental point. In everything that appertains to the main work—the grand aim of the profession—we are united by bonds that cannot be broken.

But this minor question is bringing us into a disturbed and unpleasant condition, and, without a change in tactics, it is difficult to see an immediate good result in the near future. I do not propose in this paper to go over the whole ground of our ethical differences, but only to touch upon a few salient points.

THE MEDICAL RECORD, in its editorial for December 9, 1882, seems to imply that the medical profession in the County of Kings has lately been engaged in unworthy methods, and that a prominent and honored ex-president of the Medical Society of the State of New York has, in some way, transcended his proper sphere

or influence. Still, these facts seem to remain. A majority of the members in attendance at the said meeting of the Kings County Medical Society, with deliberation, expressed themselves against the new Code, and the man alluded to is the one who, heretofore, has done more, and is now doing more, than any fellow-worker in the United States, to maintain a distinct line between those medicines which have good and genuine merits, and those which are spurious and unreliable. These facts are significant, and they must have weight with all thinking and upright medical men.

The question of instructions to delegates comes conspicuously to the surface. Does a delegate, indeed, lose his manhood if he, in a measure, forgets his own opinions in honoring the opinions of those who send him as their representative? I think not.

It has been said, and, in substance, repeated, in THE MEDICAL RECORD during the past year, that the opponents of the new Code have not offered a single sensible argument against it. This may be, in part, true, for it must be confessed that irony and sarcasm, instead of argument, on both sides, have been the main weapons in this warfare. But, if THE RECORD will allow, I will now undertake to offer what appears to me to be a sensible argument, and it is to place the two codes side by side, in their prominent features, believing that the contrast will be in favor of the old rule.

AMERICAN CODE.	CODE OF 1882.
1. Medical education essential in a physician.	1. Silence.
2. Moral character essential.	2. Silence.
3. Irregulars not to be received in consultation.	3. Legally qualified the only requirement.
4. Consultant not to impair confidence in attending physician.	4. Silence.
5. Should guard against all future unsolicited attendance.	5. Should continue his visits as long as he deems necessary.
6. Where two disagree, an umpire to be called.	6. Where two disagree, the case to be argued before the patient or family.
7. Should not take charge of another physician's patient.	7. Silence.
8. The relations of physician to patient confidential.	8. Silence.

A word of comment on each of these points. The whole medical profession believes in medical education, the more extensive the better. Our Code, which is our platform, ought to express this fact. The same may be said of all those traits which, combined, constitute moral character. Practitioners without these two qualifications ought to be classed as irregulars and unfit persons to be taken into partnership in assuming the weighty responsibility of treating human sickness. The American Code so expresses it. The new Code does not. Legal qualifications are only an outward badge. They may or they may not be genuine. Taken alone they are not a sufficient test. The experience of the medical profession, under the American Code, tends to confirm our belief that an observance of the injunction specified in my fourth point leads to the best interests of the sick, and also of the profession. As to the fifth point, there may be some good arguments on both sides. I think the position of the American Code the safer. I have no doubt of the superior wisdom of the American Code in respect to the sixth and the seventh points. If there are any differences of opinion in respect to the doctrine expressed in the eighth and last point, they must be very few and unimportant. Incidentally, in the discussions upon this subject, considerable has been said about "the leaders," the "legitimate leaders," "the would-be leaders" in the profession. It seems to me we ought to keep silent in this respect. Every man in the medical profession is expected to be governed by his own opinions on these questions, and every man has a right to make his opinions known, and to comment upon the opinions of his neighbor.

¹ This report, it is to be hoped, will put an end to the idle reports in circulation.

always, of course, in accordance with the dictates of courtesy and the rules of debate.

Having now reviewed the matter as it appears from my standpoint, I will express my thanks to you for your kindness in giving me this audience, and will refrain from taking any more of the space of your valuable journal.

T. H. SQUIRE.

ELMIRA, N. Y.

[We take great pleasure in giving place to the foregoing, inasmuch as it is a well-written and courteous exposition of one side of the controversy, which is interesting to many in this and other States, and we avail ourselves of the opportunity to more fully explain some of the points at issue. As regards the course of the "prominent and honored ex-president" referred to, we unhesitatingly believe that he "transcended his proper sphere" when he undertook to dictate to *practising* physicians the manner in which they should conduct their own affairs.

As regards the general question as to the propriety and desirability of instructing delegates, we have already given a decided opinion. It places the delegate himself in the possible position of committing an act which neither his judgment nor conscience approves. The safer and better plan is for societies to elect as delegates men whose sentiments are known to be in harmony with the prevalent opinion of their section, and then trust to their honesty and judgment to vote or act for the best. If they have delegates whose honesty and judgment they cannot trust, they have no one to blame but themselves.

In reference to Dr. Squire's interesting comparison of some of the points in the old and new Codes, we can make the general statement that we believe it was the intention of the framers of the new Code to omit matters that were already provided for by the laws of the land and by the general moral laws that all persons are supposed to be amenable to. The points numbered by Dr. Squire are all of minor importance except the one referring to the non-restrictive clause in the new Code. This clause confers upon every medical man the right to think for himself and to govern his actions strictly in accordance with the dictates of his own conscience. It is this feature alone of the new Code which is the main issue, and which we have tried to defend. Regarding all the other points, we believe that concessions can easily be obtained.—ED.]

THE NEW YORK CODE OF MEDICAL ETHICS AND FREEDOM IN CONSULTATION.

A PRESENTMENT OF THE CASE FOR THE NON-RESTRICTIVE CLAUSE IN THE NEW CODE, BY ONE OF ITS ADVOCATES.

RULES GOVERNING CONSULTATIONS.

"MEMBERS of the Medical Society of the State of New York, and of the medical societies in affiliation therewith, may meet in consultation legally qualified practitioners of medicine. Emergencies may occur in which all restrictions should, in the judgment of the practitioner, yield to the demands of humanity" (Code of Ethics of New York State Medical Society).

The section in question simply *permits* consultation with legally qualified practitioners, whatever their therapeutic methods.

"But no one can be considered as a regular practitioner or a fit associate in consultation whose practice is based on an exclusive dogma, to the rejection of the accumulated experience of the profession and of the aids actually furnished by physiology, pathology, and organic chemistry" (Code of Ethics of American Association).

The restrictive Section in the old Code forbade consultation with any but regular physicians, defining "regular" as above.

The question at issue is not primarily the utility, or

otherwise, of consulting with any but those who call themselves "regular," but concerning the advisability and justice of the individual being allowed to do so if the welfare of the patient or of the community seems to demand it; but concerning the advisability and justice of allowing every physician to decide for himself whether he will or will not do so.

REASONS FOR THE CHANGE—OBJECTIONS TO THE OLD RESTRICTION.

1. *It was inoperative.* For many years the number of cases of discipline for violation of this restriction has been extremely few. Although we have positive knowledge that consultations with so-called "irregular practitioners" quite often occur, we have been able to find no instance, occurring within recent years, when such cases have been subjected in New York State to investigation and discipline.

2. *It failed to lessen quackery.* We can find no evidence that the old restriction, while placing a formal barrier about regular medicine, has lessened the number of quacks, or injured their prosperity.

3. *It was opposed to the general judgment of the public,* who never have understood, and never can be made to understand, the technicality on which the old restriction was based. It therefore injured the standing of the profession before the world.

The people and lay press throughout the country unanimously approve the action of the State Society in removing the restriction. Such a complete unanimity of opinion among all classes upon a question of morals should not be disregarded.

4. *It affronted and made enemies of all medical men declared to be irregular.* It was a form of persecution which was just weak enough to act as a stimulus and help to the persecuted.

5. *It infringed on individual rights.* Our chartered medical societies have a right to say what shall be the moral qualifications of their members, judging them by the ordinary moral standards; but they have no right (morally) to impose a special line of conduct upon individuals and say arbitrarily that such rule of action alone is right. This establishes a technical morality which is not only unjust, but is unphilosophical and at variance with the principles of modern ethics. *Good* and *bad* are only relative terms. A certain line of conduct pursued by a hundred persons may be good in ninety cases, bad in ten. The motive is the main issue. A consultation with a "regular" physician *may* be dishonest and mercenary. Medical societies and codes may urge honesty of action and right conduct generally, but to prescribe specific things and say that they alone are always right is unwise and unjust.

6. *The definition of an irregular physician* given by the old Code does not describe all in this State who are classed as irregular. If literally interpreted it would really permit consultation with many of this class. Whatever may have been the condition of medical education and morals at the time when the "American Code" was adopted, the number of those styled "regular" does not now embrace all who are educated, honest, and trustworthy practitioners. This is demonstrable in the experience of nearly every physician who has been for even a few years in practice in this State. The attitude of the defendants of the old Code is therefore inconsistent.

7. *A legal wrong was done by the old Code,* in the opinion of eminent lawyers. The State Medical Society is a chartered institution with certain powers by which it profits. Yet it used these powers to exclude from professional recognition and to injure persons whose legal status was exactly like that of its own members.

8. *It was a hindrance* to securing medical legislation for the general elevation of the profession. This has been illustrated in Massachusetts and other States, as well as in New York.

ADVANTAGES OF THE NEW SECTION.

Its advantages are summed up in this: that it does away with the objections, just enumerated, to the old, restrictive Code.

It is in harmony with general ethical principles which urge the discharge of our duty toward ourselves and our brother rather than the assumption of a special attitude toward a class prejudged and condemned.

It places the profession beside that of France and Germany, where the policy of ignoring rather than of actively opposing homœopathy and other dogmas is successfully pursued.

It gives opportunities for showing that the surest way to vindicate the superiority of scientific medicine is to let it come in contact and comparison with charlatany.

SPECIAL CHARGES AND OBJECTIONS MADE TO THE NEW SECTION.

1. *That it was the work of specialists who wished to increase their consultation practice.*—This charge has been laboriously, persistently, and insultingly made. While it has nothing to do with the absolute merits of the question, it is, we believe, entirely false.

The Code was drawn up by a committee of five, three of whom were general practitioners; and three, also, were ex-presidents of the Society, widely known and entirely trusted.

2. *That the Code was rushed through the Society hastily, by a small vote.*—The new Code was fully discussed, at great length, in two meetings, and was adopted by a vote of fifty-two to eighteen. Some who voted against it voted for the Roosa resolution, so that the majority for a merely non-restrictive clause would really have been larger. The meeting itself was one of the largest that the Society ever held.

3. *That the new section is an entire surrender to dogmatic medicine, i.e., an acknowledgment of the truth of homœopathy, Thomsonianism, etc., and that it implies the confession of having previously held a false position.*—The new clause simply means that we believe it unwise and unjust to forbid consultations with legally qualified practitioners. It advises nothing and admits nothing beyond the principle that there may be occasions when the rights of humanity should be considered paramount to the demands of trade-unionism.

The questions of "surrendering" or "admitting," however, we repeat, have no bearing upon the absolute right or wrong of the thing done. If the previous position was really wrong, it should be only fair to admit it. It should be remembered, moreover, that society progresses and requires new adjustments.

4. *That the homœopathist or other medical dogmatist can have nothing in common with the scientific practitioner, and that consultation between the two must, a priori, be absurd, futile, or even injurious.*—The Code admits, does not advise, such consultations. It urges honesty, and if a doctor be honest and believe the above, he need not consult with dogmatic or dishonest physicians. But even admitting the above proposition so far as relates to therapeutics, it does not necessarily cover matters of diagnosis or general management. Furthermore, in this State, many so-called irregulars are not followers of dogmatic medicine.

5. *That it will lower the tone of the profession.*—It is claimed that the removal of the restriction will lower the tone of the profession and lead to moral decline and decay.

It is impossible to prove such a charge, and only declamatory statements have so far been brought forward in evidence. Experience so far shows that individual morals are not appreciably affected by Society codes. Doctors become good or bad as other persons do. The superiority of scientific medicine must be proved by its works. Societies can elevate medicine most by scientific work and criticism—which is their legitimate function. As regards ethics they can only urge general right con-

duct. The present Code continues to urge and demand this of its members; if they obey it they cannot be made worse by having the privilege of consulting as conscience dictates. On the other hand, submission to a code of ethics, which is believed to be unjust, oppressive, and opposed to the demands of conscience and the sense of humanity, is certainly not calculated to elevate the moral tone or inculcate honesty of principles.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Comparative statement of cases of contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending January 20, 1883:

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
January 13, 1883	5	9	75	1	64	54	0	0
January 20, 1883	0	10	62	9	55	43	2	0

A PROSPEROUS CHARITY.—The New York Society for Relief of Widows and Orphans of Medical Men (organized 1842), held its annual meeting in December. Whole number of members, 142; benefactors, 22. During 1882 the society has extended aid to thirteen widows and four children of deceased members. Total disbursements 1882, \$4,372.68; total assets, \$141,243.49. Jared Linsly, M.D., President, 1882; Isaac P. Taylor, M.D., 1883. We very much question whether any charitable organization in this or any other country, with so comparatively few members, can show a better record.

A PLACE IN WANT OF A DOCTOR.—From a tabular list of practitioners of the different counties in Nebraska we learn the astonishing fact that there are two entire counties in which, notwithstanding a thorough search, not a single medical practitioner, be he quack or regular, could be discovered.

AN ABORTIONIST'S ESTABLISHMENT BROKEN UP.—A remarkably prosperous abortionist establishment in Chicago, to which one Dr. George Kellogg was medical adviser, was recently broken up by the police. Such institutions are numerous in this city, but it is found extremely difficult to secure evidence enough to convict in any special cases.

CHOLERA AT PANAMA.—For several weeks cholera has prevailed at Salina Cruz, and Tehuantepec. Late reports state that the deaths at the latter place number twenty-five daily. The railway laborers have deserted and the work is at a standstill. A cordon has been established between the two towns and Oaxaca. The disease has been caused probably by the scarcity and impurity of the water.

PROPAGATION OF SMALL-POX BY THE SPARROW.—Dr. Hewson, of London, says that the sparrow may have small-pox and propagate the disease.

A PROLIFIC PARENT.—A well-to-do farmer, of seventy years of age, in Delaware, who has just married his third wife, has twenty-eight children, six by the first wife, and twenty-two by the second. For economical reasons he established a school for his children and his new bride is the teacher. Further improvements upon his scheme are possible.

A NEW HOSPITAL is to be erected in Liverpool in place of the Royal Infirmary. It is to cost \$500,000.

BISMUTH AS A SPECIFIC FOR CANCRUM ORIS.¹

By CONSTANTINE J. MACGUIRE, M.D., L.R.C.S.I.,
NEW YORK.

THE medical profession, very wisely and with good judgment, receives with caution claims to the discovery of new drugs possessing marvellous properties; and the profession is very slow to accept the statements of successful results in the treatment of diseases hitherto uncontrollable.

This is well, and as it should be. Within the memory of the present medical generation a cure for diphtheria has been found by men eminent in the profession, that is, the eminent men reported one or two cases of malignant diphtheria as recovering under their special line of treatment; but, when the same line of treatment was applied in two or three other cases of like malignancy, the same happy results were not obtained. Naturally the body of sceptics in anything new or true in medicine increased.

Again, men of repute came out in learned articles on prophylactics to scarlatina and small-pox, and, whether they themselves believed or not, the lay public had faith till they found the undertaker and his ice-box at the door. Every day we either hear or read of the discovery of a specific; but the claims of the author are found to be based on the cure of one, or perhaps two cases which might have recovered without any treatment at all; and, when the specific is applied by other hands to other cases, its vaunted efficacy is found wanting.

In presenting the histories of the following cases of cancrum oris, I should have some diffidence—considering the simplicity of the treatment, and my not giving any line of argument or reasoning in support of that treatment—had I not the good fortune to have invited a very considerable number of my medical brethren to see the cases during every stage of their progress.

If I be allowed to make an "Irish bull," curing a disease that does not exist, is not a matter of much difficulty; thus, the cure of a common tonsillitis or aphthous ulceration is often, through a mistake of diagnosis, called a cure of diphtheria. The description and history of each of the twenty-four cases I am about to relate, will unmistakably stamp them as being true cases of cancrum oris, or stomatite gangreneuse. The fatality of the first four cases, the fetor, the destruction of hard and soft tissues, the peculiar appearances of the children, starved and scrofulous, and the affection in most part following measles, complete the picture of the disease as described by the writers on the subject in this and the last centuries.

The epidemic, if I may so call it, came under my notice in the Institution of the Sisters of St. Dominick, situated at Sixty-third Street and Second Avenue, and the disease appeared first among nineteen children that had been admitted from a kind of "Shepherd's Fold," which had been condemned by the city health authorities. These children were represented, on admission, as being some weeks convalescent from measles, and when first seen by me at the institution, presented a

most pitiable and wretched condition. They were markedly attenuated, bloated, pale and sallow, and suffering from diarrhoea and cough. The unfortunate creatures, it seems, became, from the neglect and starvation they had suffered in the "Fold," so debased and degraded that they ate their own excretions. I had them placed in a ward of the institution isolated from the other inmates, and ordered them a generous diet.

January 21, 1882.—Measles showed itself; four or five children were affected, and at the same time the Sisters reported that three of the most starved and debilitated, viz., Joseph M—, Mary F—, and Annie S—, had "sore mouths." Joseph M—, the first child examined, I found to have a grayish black ulcer, about the size of a silver dime, on the oral mucous membrane, three-quarters of an inch from the angle of the mouth, on the right side of the face. The upper lip was swollen, the teeth decayed, the gums red, spongy, and covered at the edges, with a dirty, grayish, pulaceous deposit. The gums in the rear of the teeth were not then affected. Pulse, 110; temperature, 101° F.; fetor from mouth very offensive; child suffered intense thirst and drank any fluid with avidity; saliva flowing constantly.

Treatment.—Mouth washed out every two hours with solution of carbolic acid, ulcerated surface touched with nitrate of silver, four grains of chlorate of potash with cinchona every three hours; beef-tea, milk punch, and milk *ad libitum*.

January 22d.—Passed restless night; thirst insatiable; the child, if left a moment alone, gets out of bed and roams over the ward in quest of drink; upper lip much more swollen, and two incisor teeth loose, which were removed. Ulceration has already eaten from anterior to posterior aspect of gums; and ulcer on inside of cheek increased to the size of a twenty-five cent piece without any defined edge, but filled up with a disintegrated, grayish-black, broken-down tissue. Fetor very much increased, in fact, so bad that, notwithstanding the use of Condy's solution and Platt's chlorides, the ward is insufferable. Patient takes nourishment freely. Treatment continued.

January 23d.—Gangrene increased; the sore on buccal surface and that on upper lip now continuous, and presenting a most foul and loathsome appearance; fetor simply intolerable. Clipped off with scissors the broken-down, pulpy mass over the sore, and cauterized with nitric acid. Otherwise continued treatment as before.

January 24th.—Small dark spot showed itself at right ala nasi, and half an inch directly outward on cheek another. Fetor unbearable. Ordered a solution of permanganate of potash for cleaning mouth; removed three more teeth.

January 25th.—Gangrene increasing rapidly. Quinine substituted for chlorate of potash.

January 26th.—Whole upper lip one dark mass of gangrene; tongue black; cheek much more swollen; fetor, if possible, much more abominable; temperature, 101° F.; pulse, 116. Still takes nourishment with avidity.

January 27th.—Gangrenous erosion spreading; right ala nasi and adjacent parts of cheek one black slough; thirst seemingly the only cause of suffering. Except in the matter of increase in the extent of gangrenous ulceration and gradual exhaustion, there was no alteration in patient's condition up to February 1st, when he died.

Annie S— (aged two years and six months) on

¹ Read before the Yorkville Medical Association.

January 19th had, on left side of mouth, an ulcer about the size of a ten cent silver piece. Flow of saliva copious; fetor of breath offensive, general appearance wretched; skin loose, flaccid, and giving one the impression of its being the only covering of the bones. Debility and wasting so marked that there seemed to be a complete absence of muscular tissue. Tongue moist; temperature, 99° F.; pulse, 104. Coughs considerable; soft bronchial râles over chest.

Treatment.—Sedative expectorant mixture; ulcer touched with solid stick of nitrate of silver; lotion of chlorate of potash [fifteen grains to ounce], to be used as mouth-wash every three hours; syrup. ferri iodidi, internally; full diet, milk punch, and milk *ad libitum*.

January 20th.—Sloughing very much extended; cheek swollen and glassy; eye nearly closed; bright red spot in the centre of swollen cheek; and, though slough on inside of cheek would give the idea of abscess, no fluctuation could be found. Mouth thoroughly washed out with solution of carbolic acid, and gangrenous ulcerated surface, which now extended over half the oral surface of cheek, well covered with iodoform. No dressing could be well applied to the ulcerated surface, as the broken-down, disintegrated tissue stood boldly out.

January 21st.—Swelling of cheek much increased, appearance glazed or oily; lower eyelid puffed and œdematous; gum on upper jaw of affected side red, soft, and pulpy; teeth somewhat loose; fetor horribly offensive. Removed broken-down tissue and loose teeth, and covered ulcerated surface with iodoform. Otherwise treatment as before.

January 22d.—Bright red spot on centre of cheek has become darkish green and is about the size of a bean; gangrene occupies whole of inside of cheek; three teeth so loose that I removed them with my fingers; shreds of broken-down tissue hanging in strings from side of cheek. Child tears and actually swallows them. Thirst insatiable; raves and is very restless. Ordered a little morphia; treatment otherwise as before.

January 23d.—Black spot on cheek now the size of a quarter of a dollar; surrounding tissue from its edge to the angle of mouth showing unmistakable signs of becoming one gangrenous mass; temperature, 101° F.; pulse, 106. Tongue dark brown, mouth constantly open; cough not increased, soft mucous râles over chest, no pneumonia; bowels tending to diarrhoea, and abdomen somewhat tympanitic. Except in cleansing the mouth with disinfectants to lessen the horrible fetor, and giving stimulants, all treatment was abandoned.

January 24th.—Lower eyelid and cheek to angle of mouth, one black, rotten, loathsome, gangrenous mass. Child still takes drink. Pulse very feeble, 114; temperature, 101½° F. Stench in the ward, notwithstanding the use of carbolic acid and Condy's solution, simply intolerable; nurse in charge of ward sick and vomiting.

January 25th.—Child died; bronchial effusion taking place six hours before death.

February 20th.—Mary F., aged two and a half years; a wasted, shrivelled little child, with shrill voice and precocious manner, was examined. Gum on outer aspect of molar teeth found to be soft, pulpy and detached, grayish in color, smelling foully, in fact gangrenous. Touching parts with probe and making examination did not seem to give pain. At the angle of mouth, small grayish ulcer; tongue on same side ulcerated; fetor of breath; discharge of saliva very copious, and most offensive; ulcers at angle of mouth and side of tongue are indurated; no perceptible swelling of cheek. Temp., 99° F.; pulse, 100.

Treatment.—Mouth well cleansed with carbolic acid; ulcers touched with nitrate of silver; pulv. cret. c. opii and bismuth subnitrate internally, arrowroot and milk-punch.

February 21st.—Ulcer on tongue looks better; those on gum and inside of cheek larger, and seem to be digging into the tissues; teeth are becoming loose; diar-

rhœa checked; pulse fuller, temperature normal. Removed three diseased and loose teeth. Syrup. ferri iodidi internally, otherwise treatment as before.

February 22d.—Gum, whence teeth were removed, one dark grayish mass of gangrenous tissue, which stands out loose and free from the alveolar process; pieces come away easily with dressing-forceps without giving any pain; ulcer on side of tongue healing; that on cheek enlarged and extending well under upper lip. Treatment: dead tissue cut away, parts touched with hydrochloric acid, and application of chloride of lime made.

February 23d.—Ulcers increasing rapidly; cheek and upper lip on affected side much more swollen. Mouth well cleaned out; broken down tissue removed with scissors; child chloroformed, and nitric acid applied; otherwise treatment as before.

February 24th.—Sloughing of cheek seems checked, though parts are very much swollen; sides and base of ulcer have taken on a somewhat healthy look; alveolar process bare. Temperature, 100° F.; pulse, 100. Treatment continued.

February 25th.—Cheek quite hard and tense; no new grayish pulpy matter in sore; but on the outside, at a point corresponding to middle of ulcer on inside, a small grayish black spot appeared. Eye on affected side closed; tongue has again become affected, and evidently exfoliation of alveolar process is taking place. Application of sulphate of copper with cinchona; otherwise treatment as before.

February 26th.—Black spot on cheek as large as a twenty-five cent piece; inside of mouth seems one loathsome mass of gangrene, emitting such a foul, sickening odor, that no disinfectant seems capable of lessening it. From this date to February 1st, when the child died, gangrene simply ate its way, increasing steadily, till the whole side of the face looked as though it had been cut out and the part filled up with lamp-black.

Before proceeding to the relation of the fourth and last fatal case, I wish to give a very short and succinct epitome of the views of the authors I consulted on the disease and the treatment recommended and followed by them. As a rule, I found that most of the writers on diseases incidental to childhood, even those held highest in professional esteem, either partially ignored, slurred over, or devoted a quarter of a column to the disease, or boldly stated that therapeutics could not control, check, or cure it.

Dr. Elliotson, in the "London Hospital Reports for 1833-34," gives the history of a case, the exact counterpart of those related by me, traced from day to day, recording the same ruthless destruction of tissue, and the same impotency of medicine to stay its course. Dr. Elliotson in his lecture introduces the disease "*Cancrum Oris*," or, "*Stomatite Gangreneuse*" to his hearers as one fortunately seldom met with. He says: "It is a disease, I am sorry to say, which I have never seen cured, though cases are related where patients have recovered from it." He goes on then to relate the case of a child seventeen months old, recovering from scarlet fever, attacked with a small ulcer on the oral mucous membrane, and ulceration extending along the alveolar process of upper jaw, teeth falling out, exfoliation taking place, gangrenous erosion extending over the whole cheek and lower eyelid, death ensuing thirteen days from inception of disease, notwithstanding that what is designated as active and heroic treatment was promptly and persistently brought into requisition. Elliotson refers to Dr. Cummings, of Dublin, as being then the most correct and lucid writer on the disease. Dr. Cummings holds that the disease is only met with in children between twenty months and seven years of age, who have lived in an impure and polluted atmosphere, and on poor and insufficient diet, and even then it is only met with as a sequence to measles or scarlatina. Dr. Cummings seems to have been anticipated by Huxham, who, in a report made in 1745, observed: "I have more than once during

this month witnessed a mortification of the mouth and fauces, besides caries of the cheek and os vomeris, which occasioned a very painful death, and that, too, after measles.

Dr. Willan, who writes about the same period, says: "In one infant, about the eleventh month, a considerable erysipelatous swelling affected the left cheek, and within three days produced a deep gangrenous eschar and death."

Dr. Cummings describes three varieties of the disease; one in which the gums are first affected and become purplish and spongy, and, with proper treatment, a fair percentage of such cases recover. What the proper treatment is he does not state. The second variety corresponds to the cases I have been describing, and the third is where the pudendum is involved. Just here I wish to have this last point borne in mind, because, in one of the cases I will present, such a complication ensued. All the writers who mention the disease concur in stating that an active local treatment has proved the most efficacious, together with the administering of tonics, pushing them, as Elliotson says, to their fullest extent, and placing the patient on generous, strengthening diet—beef-tea, port wine, etc. Taupin claims good results from a very heroic treatment of caustic applications; but Tourdes, writing after him, having met with a great many cases, says, that notwithstanding Taupin the ravages of the disease have not been one whit less. Tourdes himself recommends simply mouth washes, caustic applications, tonics, and strengthening diet. Niemeyer, West, Tanner, and Bohn, all give a similar line of treatment. Statistics of the results obtained by some of the best known authors I will give later on.

Dennis G—, aged three, was admitted to the infirmary April 12th, suffering from measles. Child was fat, stout, and in general good condition. Rubeola was mild and ran its usual course, the child being up and around the ward on the 18th, eating well, and, to all appearances, convalescent.

April 20th.—Refused food; skin hot; temperature, 101° F.; pulse, 108; tongue moist; right cheek swollen, inflamed, and small ulcer on inside showing a grayish white deposit. Ulcer touched with solution of nitrate of silver (40 grs. to 1 oz.); chlorate of potash wash; quinine and iron, internally. Temperature, 100° F.; pulse, 104; slight diarrhoea.

April 21st.—Ulcer on inside of cheek about the size of a dime. Takes nourishment freely—beef-tea, wine, etc. Gums of superior maxilla in region of molar teeth, soft, pulpy, swollen, and grayish in color; fetor most offensive. Mouth well washed out with tepid water, and afterward with weak solution of permanganate of potash.

April 22d.—Cheek not so hard; swelling somewhat less; ulcer on inside of cheek not increased; gums soft, free of hard parts, and bleed on pressure. Treatment as before.

April 23d.—Condition of cheek unchanged; gums of superior maxilla gangrenous; molar teeth loose; loose teeth extracted; gangrenous tissue clipped off with scissors and touched with chloride of zinc. Otherwise treatment as before.

April 24th.—No particular change, except that ulcer on inside of cheek has a healthier appearance; grayish slough cleared away, and induration not so marked. Sleeps better.

April 27th.—Necrosis of superior maxilla; a piece, an inch and one-half, removed; more dead tissue cut away; parts touched with nitrate of silver. Otherwise no change in treatment.

April 29th.—Swelling and induration of cheek much less; ulcer on buccal surface healing; gangrenous ulceration of gums looking much better; temperature, 99° F.; pulse, 100; taking food well. Treatment continued.

April 30th.—Patient doing well, and continued so to May 7th, when he contracted a slight bronchitis.

May 8th.—Cheek again swollen and hard; eye partly closed; loathsome, offensive odor returned in greater intensity; on inside of cheek a grayish, black spot, size of a twenty-five-cent piece; gums, that before seemed healing, rapidly taking on gangrenous look. Treatment as in the early stage, except a solution of copper with cinchona substituted for the nitrate of silver application.

May 10th.—Gangrene rapidly spreading; child restless and suffering from great thirst. At the suggestion of my colleague, Dr. Ripley, put on five minims of phenic acid every two hours. Otherwise no change in treatment. From this date to May 16th, when the child died, the gangrene continued to spread till the whole side of the cheek, lower eyelid, right side of the nose, and upper lip were one black mass. On the 15th a black spot, not larger than a dime, appeared on the chin, and, on the following day, when the child died, it was fully as large as a fifty-cent piece.

During the progress of the last case, I had two others equally unpromising, whose histories from April 17th to May 10th were identical with those of Dennis G— and the other fatal cases I had in January. There was the same grayish slough on the inside of the cheek, the same gangrenous condition of the gums, the same hard glassy swelling of the cheek, and the insatiable thirst, the same fact of its being the sequence of measles, and the children presenting, if possible, a more wretched, scrofulous, and miserable physique. These two were Arthur W—, aged four years, and Nellie H—, aged three years and four months. They occupied beds in the same ward with Dennis G—, and were subjected to nearly the same treatment as he was. The general treatment of support, tonics, and stimulants was exactly the same; while the local applications—disinfecting washes and escharotics—varied somewhat, without producing any appreciable difference, better or worse. Indeed, so disastrous had been our results in the face of our having zealously carried out the system of treatment recommended by standard authors, and of my having availed myself of the kind and able counsel of my medical brethren who saw the cases that I commenced to look upon any child attacked as an inevitable victim.

On May 11th I was informed upon my entrance to the ward that still another child was, in the words of the sister, "getting the frightful disease in the mouth." This child, Katie H—, aged seven years, I examined and found she had a small ulcer on the inside of the left cheek, with all the characteristics described in the early stages of the other cases. I confess I was in despair. On consideration, I came to the conclusion that following in the old rut of treatment was almost useless, if not quite so. By a process of reasoning, or by accident if you will, I conceived the idea of applying locally the subnitrate of bismuth. After thoroughly cleansing the mouth with a disinfectant lotion, I covered the ulcerated surface with this drug, and the next day, May 12th, the grayish slough had partly cleared away, and the fetor, which had been most disagreeable, was sensibly lessened. The hardness of the cheek, if not less, had not increased, and the child was not so thirsty. Temperature, 99° F.; pulse, 90. Gum on upper jaw reddish purple, soft and tender. Mouth washed out with solution of carbolic acid; bismuth applied every three hours, syr. ferri iodid., cod-liver oil, and generous diet.

May 13th.—Fetor markedly less.

May 14th.—Much better, sleeps well, ulcerated parts getting a healthy appearance. From this date to the 1st of June, when she was discharged, thoroughly cured, the patient did well.

On May 12th, after witnessing the happy change effected by the bismuth in the case of Katie H—, I determined to try its efficacy on Arthur W— and Nellie H—, both of whose cases we looked upon as hopeless.

On May 10th I had removed some teeth together with a large piece of the superior maxilla from Arthur W—.

His cheek was then swollen tense, a large black gangrenous ulcer was on its inside surface, and his eye was nearly closed. The stench from him was intolerable. Usual disinfecting and supporting treatment continued.

May 11th.—No change.

May 12th.—Filled up cavity in cheek with bismuth, first cleansing it out well with disinfectant wash, and repeated every three hours.

May 13th.—No marked change, except odor a little lessened.

May 14th.—No increase of gangrenous erosion! Treatment continued. Separation of a large mass of grayish black slough from ulcer on cheek and cavity whence exfoliated bone was removed. Parts looking healthier, fetor less.

May 18th.—Fetor nearly disappeared in toto! Takes food freely; sleeps better; ulcer assuming a very healthy appearance; swelling and hardness of the tissues of the cheek rapidly subsiding.

May 25th.—Ulcer on inside of cheek quite filled out and granulating kindly. Removed small piece of dead bone from superior maxilla. Otherwise doing well. Treatment continued. From this date to July 1st, when discharged cured, the patient did excellently well. Since then he has been taking cod-liver oil, and is now in perfect health.

Nellie H.—ran the same course up to May 12th, as the two preceding. Her condition at that time was identically the same—black gangrenous slough on buccal mucous membrane, swelled cheek, etc. Applied treatment as in the last case.

May 13th.—Clipped away with scissors a considerable amount of disintegrated tissue, then packed parts with bismuth. Continued treatment to 17th, when I removed a large piece of exfoliated bone and several teeth from inferior maxilla. From this date to June 15th, she slowly but steadily improved, the bismuth being regularly applied, and the mouth thoroughly syringed. Iron, cod-liver oil, and generous stimulating diet administered. She is now one of the healthiest children in the institution, though showing the loss of hard and soft tissue, but *not* showing the horrible deformity which formerly cases that had advanced to this stage and recovered presented.

The next case is of interest, because it goes a long way to prove that the disease is contagious, and that it does occur in children beyond the age of seven years. Mamie C.—, aged thirteen, a strong healthy girl, who assisted in taking charge of the children suffering from gangrenous sore mouth, was reported sick, June 5th. She stated she had been feeling unwell for a few days, that her mouth was sore and constantly running water, that she felt constant thirst, and could not sleep. On examination found inside of cheek ulcerated; tongue brownish, ulcerated and indurated; gums soft, swollen, and pulpy. Fetor excessively offensive, could hardly open mouth, cheek swollen. Temperature, 103° F.; pulse, 120; slight diarrhoea. Bismuth packed into ulcerated surfaces, mouth washed out with solution of permanganate of potash. Pulv. cretæ aromat. cum opii, internally.

June 6th.—Spent very bad night, restless and raving; so painful to open mouth that she has to be forced to allow it dressed. Ulceration of tongue and cheek spreading; mouth forcibly opened and syringed out; ulcers dressed with bismuth.

June 7th.—Fetor less. Can open mouth with less pain. Still raves at night. Has an immense flow of saliva. Cheeks and tongue on both sides indurated and trenched by a long serpiginous ulcer. Dressing of ulcers forcibly made every three hours.

June 8th.—Fetor in great part disappeared, general condition much better. The tongue and cheek on right side pretty well one mass of ulceration; but losing the appearance of a gangrene, and taking on a healthy look. Pulse weak, 120; temperature, 102° F. Takes nourishment with great difficulty, sleeps without sedative. Bismuth continued. Bark and ammonia in effervescence

every three hours. From this date she slowly improved; the ulcers healing kindly, leaving very little trace. The teeth remained intact, though the gums were badly affected. While suffering in her worst stage, I had her examined by several of my medical friends, who all agreed in the diagnosis of genuine cancrum oris. She is now in perfect health.

Josephine C.—, aged eleven, in June had a very mild attack of measles, and after the usual course was discharged cured to the body of the house July 3d, she was sent to the infirmary, complaining of sore mouth. On examination, lower lip was found indurated and swollen, with a blackish ulcer, the size of a dime, on its inside surface. Specks of red granulation stood up at points, and a thin sero-sanguineous discharge flowed down the chin. The gum, in front of the two incisor teeth, was slightly broken down and pulpy; teeth were not loose. Tongue coated; slight diarrhoea; pulse and temperature normal; fetor very offensive. Mouth well washed out with solution of permanganate of potash, and gangrenous ulcer dressed with bismuth every three hours. Syrup. ferri iodidi and cod-liver oil, internally.

July 4th.—Except that fetor was markedly less, there was no alteration.

July 5th.—Very feverish; temperature, 102° F.; pulse, 120. Tongue coated and badly ulcerated on right side; bases of ulcers hard; under lip looks exactly like epithelioma. In trying to find cause for heightened pulse and temperature, discovered that the child was concealing a phlegmonoid inflammation of pudendum. Labia swollen to size of an orange on either side, and the contiguous surfaces covered with what looked like a diphtheritic membrane. Parts felt elastic, but no fluctuation could be discovered. Lint smeared with vaseline introduced between labia, and hot poultices applied.

July 6th.—Condition unchanged.

July 7th.—Consultation with my colleague, Dr. Ripley, as to lancing labia. Determined on expectant treatment, continuing poultices and dusting labia with bismuth.

July 8th.—Swelling and tenderness of labia perceptibly lessened, ulcer on lip unchanged.

July 12th.—Inflammation of vulva nearly well; ulcer on lower lip increased; small sore about the middle of buccal mucous membrane; no fetor. Treatment continued.

July 15th.—Child allowed out with parents for twenty-four hours.

July 16th.—Ulcer on lower lip extended to that on cheek and now reaching angle of jaw; gums on same side a whitish-gray ulcerous mass. Parts well washed with permanganate of potash, and then dressed with bismuth; which treatment was continued up to

August 4th.—A large sore appeared on hard palate filled with grayish pulpy disintegrated tissue. Clipped away broken-down tissue and dressed with bismuth; continued application every three hours. The parts are now healed, showing, on hard palate, a loss of soft tissue about the size of a dime, and, on cheek and lip, cicatrices. There is no deformity, the disease being absolutely controlled before osseous tissues were affected. This is a case that, I believe, demonstrates beyond cavil, that *bismuth* is a disinfectant, a deodorizer, and, unquestionably, an agent that cannot only check, but absolutely annihilate the progress of a rodent ulcer. The child now shows the cicatrices on lip and cheek, and a healed cavity on the hard palate.

That this paper may not, by repetition, be prolonged to a tediousness beyond toleration, I am compelled now to give simply names, ages, location of disease, and results. Most of the cases thus summarily disposed of, have been seen by a large number of practitioners and were under the joint care of Dr. Ripley, Dr. Gleises, and myself.

Katie L.—, aged seven years, was admitted to the infirmary June 20th with the same small sore on buccal

surface common to the other cases; the gums were badly affected. Treatment: Generous diet, cod-liver oil, syrup, ferri iodidi internally, and application of *bismuth*, the mouth being washed with solution of carbolic acid. Discharged July 11th, cured. There was *no* loss of hard, and very little of soft tissue; simply the bluish cicatrix showing along the inside of cheek. Her gums were badly affected, yet she lost no teeth!

Mary M—, aged six years, admitted June 29th. Vicious-looking ulcer on, inside and about the centre of cheek; inferior maxilla in the region of the molars also affected. All the characteristics of the disease were present. Treatment same as above, and the patient was discharged thoroughly cured July 7th, just eight days from the commencement of the attack.

Mary R—, aged four years, admitted June 20th. Small sore on inside of left cheek; gums to some extent affected; fetor very offensive. Treatment same as above. On the third day the fetor was almost imperceptible; the parts had assumed a healthy appearance, and she continued to improve gradually up to about July 3d, when she was discharged cured.

Gertrude F—, aged two years and six months, admitted June 29th. All symptoms of the disease present. Gums of inferior maxilla, in the region of the incisors, badly affected. Continued the treatment we had adopted. Mouth well washed with solution of permanganate of potash. Bismuth applied to ulcerated parts every three hours. Cod-liver oil and syrup, ferri iodidi internally. Cured in three weeks. No loss of hard or soft tissue.

Maggie W—, aged about three years, admitted July 2d, suffering from sore on buccal surface. Cheek swollen; fetor as usual. Treatment as above. Discharged cured about July 22d.

Sarah K—, Robert B—, Lillie E—, and Edward D— were all admitted about the same period. Examinations showed the same grayish slough on inside of cheek, the gums in gangrenous condition, the patients exhibiting all the characteristics I have before fully described. The disease yielded promptly to the "*bismuth* treatment" and the ulcers were all thoroughly healed in from two to four weeks. Concerning the remaining six cases, it is only necessary to say that they all occurred during the month of July and August, and that the bismuth treatment effectually controlled the disease. In all the foregoing, I have confined myself to bare facts, daily notes, simple and uncolored, of successful and unsuccessful cases. I do not claim to be able to submit a theory which can scientifically account for the marvellously fortunate results of the line of treatment I adopted; nor do I know to which of the component parts of the drug, used with such happy effect, is due the credit.

My colleague, Dr. Ripley, in the experiments made by him on different solutions containing bacteria, found that bismuth did not exhibit the properties of a germicide, but rather exercised a temporary inhibitory action.

But I do maintain that, on comparing the results obtained in the large number of cases treated by me with those recorded by the principal writers on the subject in this and the past medical generation, a percentage of recoveries is found hitherto not met with. The statistics of the disease are necessarily meagre. In private practice *cancrum oris* is rare, and it seldom happens that even those having large hospital experience meet with more than two or three isolated cases in a long career. The only authority whom I found to claim any measure of success was Dr. Hunt, mentioned in Vallex's "*Guide du Médecin Practicien*," who states that twenty to sixty grains of chlorate of potash given in the twenty-four hours controls the disease. In the early cases under my care I so administered chlorate of potash, but the result was fatal. West records ten cases, with eight deaths. Squares, out of three cases lost two. Ripley reported a successful case in *THE RECORD* of 1875, p. 266. Elliotson unreservedly states that he never saw a true case of *cancrum oris* cured; but that he heard of cases being

cured. Vallex sums up the prognosis of stomatite gangreneuse as follows: "Un résultat numérique qui peut donner une juste idée de la gravité de la maladie, est celui qu'a obtenu M. J. Tourdes, en rassemblant des observations empruntées à un grand nombre d'auteurs. Sur 239 cas, la mort a eu lieu 176 fois, et la guérison seulement 63 fois."

I have had under my personal care twenty-four cases, and of those lost four; lost those four previous to the bismuth treatment. How those four fatal cases were treated I have already related fully. Of the twenty successful cases, those showing most clearly the traces and characteristics of true *cancrum oris*, are still in the institution.

The appended microscopic report of examination of the gangrenous tissue taken from one of the fatal cases was made by my colleague, Dr. J. H. Ripley.

The specimens examined were transverse sections from the central portion of the diseased part, and included the entire thickness of the cheek. All the tissues were seen to be infiltrated with bacteria, the infiltration becoming more dense towards the internal surface. In the deeper tissues large colonies of these organisms were observed, occupying nearly circular or irregular angular spaces. Here, too, the tissues began to show evidences of inflammatory and ulcerative processes; they were partly broken down, and filled with granular debris, inflammatory corpuscles, and fat globules. In the deepest parts there was complete disintegration of the muscular structures, large detached masses lying floating in a pul-taceous fluid.

CONVALLARIA MAIALIS.

THE RESULTS OF CLINICAL EXPERIMENTS AT THE ROOSEVELT HOSPITAL, NEW YORK.

By HENRY LING TAYLOR, M.D.,

LATE HOUSE PHYSICIAN, ROOSEVELT HOSPITAL.

(Continued from p. 89.)

CASE VIII.—*Mitral regurgitation*.—Sarah G—, fifty years of age; Ireland; widow; laundress. Admitted September 29, 1882. Palpitation last five months. Expectoration of frothy material, cedema of feet and legs, and diminution in amount of urine for last three months. Shortness of breath and orthopnoea for a month past. Has also had attacks of dizziness and vomiting. Had rheumatism thirty years ago, and many times since.

Present condition.—Orthopnoea; lower limbs very cedematous; pulse very weak and irregular, 84 to the minute; respiration, 24; temperature, 97.9°, A.M. Urine, 1,010; neutral; trace of albumen. Physical examination: Heart action rapid, diffuse, very irregular. One radial pulse-beat to two or three heart-beats. Systolic murmur at apex. A few fine râles at bases of both lungs.

Treatment.—Rest in bed. Convallaria, ℥ xv. q. 4 h. October 2d.—Heart much quieter and cedema less. October 5th.—Much better; can sleep lying down. October 7th.—Convallaria stopped. October 11th.—Patient up and about, feeling pretty well. Pulse bad. Convallaria, ℥ x. q. 4 h., ordered. October 13th.—Patient not feeling so well; not affected by the convallaria; ordered it stopped for twenty-four hours.

October 14th, P.M.—Convallaria, ℥ x. q. 4 h. October 15th.—Patient has great trouble with breathing; cannot lie down. Ordered convallaria, ℥ xx. q. 4 h. October 17th.—Patient in great distress; vomits. October 18th.—Sits up all night; sleeps only by snatches. Feet and legs very cedematous. October 19th.—Put on nitro-glycerine ℥ j. of the one per cent. alcoholic solution (diluted with water), t.i.d. Convallaria stopped.

October 23d.—Nitro-glycerine increased to ℥ j. four times a day.

October 25th.—No effect. Nitro-glycerine stopped. Ordered tincture of digitalis, ℥ x. t.i.d.

October 27th.—Patient has been in a fearful condition for the last ten days. General anasarca below waist. Skin of legs tense and shiny from pressure. Has not left her chair. Pulse and breathing very bad. Her death has been expected from hour to hour. Ordered tincture of digitalis increased to ℥xx. q. 4 h.

October 28th.—Legs punctured with needle.

October 30th.—Much serum has drained away. Pulse very much better.

November 3d.—Able to lie down yesterday, and slept last night. Feels entirely comfortable. Pulse good.

November 11th.—Pulse regular and slow. No œdema of legs.

December 4th.—Urine, 1,022; acid; albumen, trace. Up and about for some time past.

December 7th.—Remains perfectly comfortable. Discharged improved.

Patient passed a fair amount of urine up to October 8th; after that seldom over twenty ounces, often less, till November 4th; since then forty to fifty ounces daily. Pulse record of little interest, as the pulse was so weak and irregular, until the patient came under the influence of the digitalis, that it could not be accurately counted.

This was a most extraordinary case. I have seen very few patients so sick as this one recover. Convallaria seemed to do good at first; it afterwards failed in the doses given; while digitalis (and puncturing the legs) succeeded brilliantly. For the converse, see Case XI., which was equally desperate.

CASE IX.—*Mitral obstruction*.—James W.—, aged twenty-nine; United States; single; block-cutter. Admitted October 28, 1882. Rheumatism in right ankle, lasting two or three days, one year ago; since then palpitation. Fair health till three weeks ago; since then cough, frothy expectoration, œdema of legs, nausea, etc. No change in amount of urine noticed.

Present condition.—Face and hands dusky. Great dyspnoea. Pulse weak. (Edema of legs. Pulse, 112; respiration, 30; temperature, 98.4°, P.M. Urine, 1,022; alkaline; albumen trace; a few granular casts. Physical examination: Heart enlarged and beating too rapidly. Systolic murmur between apex and sternum (tricuspid regurgitation). Force of heart-action very great compared with strength of pulse. Subcrepitant râles bases of both lungs.

Treatment.—Rest in bed. Milk diet. Convallaria, ℥v. q. 4 h.

October 30th.—No improvement in pulse or breathing. Orthopnoea. Sputa bloody. Convallaria, ℥ x. q. 4 h.

October 31st.—Convallaria, ℥ xx. q. 4 h.

November 1st.—Continuous cough; bloody expectoration. Orthopnoea. No sleep for two nights. Pulse stronger. Dr. Delafield diagnoses nearly complete mitral stenosis. Convallaria stopped; put on iodide of potassium, gr. v. t.i.d.

November 5th.—Patient became more and more œdematous; dyspnoea and pulse grew worse till death, at 8 P.M.

Pulse ran from 104 to 136, respirations from 20 to 40. Urine was to a considerable extent passed in bed; ten to twenty ounces daily were measured.

Autopsy by Dr. Delafield.—Right ventricle dilated and hypertrophied; tricuspid opening very large; left ventricle small. Mitral valve thickened and stenosed, nearly closed. Double hydrothorax. Chronic congestion of kidneys. General anasarca.

CASE X.—*Aortic stenosis (?)—Pregnancy*.—Anna R.—, aged forty-one, admitted October 2, 1882. Said to be six months pregnant. Well up to four months ago, when she had a sharp pain in left hip, which kept her from walking and confined her to her chair or bed. Joint was not hot, red, or swollen. This pain left her after

two months. Three months ago patient's feet began to swell, the left preceding the right by three weeks. Denies dyspnoea and palpitation. Has not left her chair for three months. For a time passed less urine than normal; now passes more than she did.

Present condition.—Great œdema of lower extremities. Pressure sore on left heel of nearly three months' standing. Pulse, regular. Temperature, 99.3°, A.M. Urine, 1,011; neutral; no albumen. Physical examination: Systolic murmur at base and down left side of sternum.

Treatment.—Rest in bed. Convallaria, ℥ x. q. 4 h.

October 6th.—Convallaria stopped. (Edema very much less.

October 15th.—(Edema almost entirely gone.

November 23d.—No œdema for over a month. Patient entirely comfortable. Discharged cured (?).

CASE XI.—*Aortic stenosis*.—John S.—, aged fifty-two; United States; married; watchman. Admitted September 5, 1882. Never had rheumatism. Has had palpitation and dyspnoea off and on for many years. Feet swelled last spring.

Present condition.—Short of breath. Radial pulse very small and irregular. Pulse, 56; respiration, 28; temperature, 96.9°, P.M.: Urine, 1,029; acid; albumen, 8 per cent.; no casts found. Physical examination: Heart apex in fifth space five inches from median line; heart beats violently and irregularly. Radial pulse less frequent than heart-beats. No murmurs.

Treatment.—Rest in bed. Whiskey, ̄ ss. q. 2 h. and

R. Morph. sulph. gr. ̄
Pot. citrat. ̄ ij.
Am. carb. gr. xl.
Aquæ ad ̄ ij.
Sig.— ̄ ij. t.i.d.

September 10th.—Heart very weak. Urgent dyspnoea; cannot lie down.

September 11th.—Infusion of digitalis, ̄ ij. q. 3 h.

September 12th.—Constant hiccupping last two days.

September 14th.—Pulse a little better.

September 15th.—Patient has not been expected to live more than a few hours for several days past. Radial pulse could not be counted most of the time. Medicine, except whiskey, stopped; put on convallaria, ℥ x. q. 4 h.

September 16th.—Pulse already much better. Whiskey, ̄ ss. q. 3 h.

September 18th.—Pulse very slow and regular. Convallaria reduced to ℥ x. t.i.d. Hiccupping stopped today.

September 21st.—Convallaria, ℥ x. night and morning.

September 22d.—Pulse good; patient feels quite comfortable.

October 5th.—Patient has continued to do well. Convallaria stopped.

October 8th.—Patient up and about; whiskey stopped.

October 16th.—Heart again beats rapidly and irregularly. Pulse much slower than heart.

October 20th.—Feels some palpitation. Feet swell during the day. Patient put to bed.

October 22d.—Very short of breath; pulse weak and irregular. Ordered convallaria, $\mathfrak{M}$ x. t.i.d.

October 24th.—Breathes more easily and feels a little better to-day.

November 7th.—Convallaria, $\mathfrak{M}$ x. four times a day.

November 8th.—Convallaria, $\mathfrak{M}$ x. q. 4 h.

November 13th.—Pulse very poor; dyspnoea. Convallaria, $\mathfrak{M}$ xx. t.i.d.

November 14th.—Pulse poor; orthopnoea. Convallaria, $\mathfrak{M}$ x. q. h. at 10, 11 and 12 P.M., then q. 2 h.

November 15th.—Vomiting.

November 18th.—General condition about the same. Convallaria, $\mathfrak{J}$ j. t.i.d.

November 22d.—Now quite comfortable. Pulse and breathing better.

December 12th.—Up and about; very comfortable. Pulse slow and tolerably regular. Breathing easy. Wants to go home. Still gets convallaria, $\mathfrak{J}$ j. t.i.d.

December 14th.—Discharged improved.

The urine was measured from September 21st to October 13th. It was always passed in fair amount, usually thirty to forty ounces a day.

DATE.	Pulse.	Respirations.
September 5th, P.M.	56	28
September 6th, A.M.	68	26

September 20th, P.M.	36	18
September 21st, A.M.	44	20
September 21st, P.M.	40	24

The pulse continued at this rate till the 27th; from then till October 9th it was 50-60; and from October 9th to 14th it was 56-68 usually. After that it was not taken.

CASE XII.—*Lobar pneumonia*.—Ellen O'D.—, aged fifty-five; Ireland; widow; domestic. Admitted September 24, 1882. Exposed to wet September 23d. Had not felt well for two days previously. Diarrhoea and pain in back and in right iliac region for last day or two.

Present condition.—Tongue coated and slightly dry. Pulse cannot be counted at wrist; weak and irregular. Appetite poor. Pulse, —; respiration, 32; temperature, 102.5°, A.M. Urine, 1,015; acid; trace of albumen. Physical examination: Dulness, absent breathing, friction râles below inferior angle of scapula right side; exaggerated breathing left lung. Sibillant breathing upper part of both lungs.

Treatment.—Milk diet. Rest in bed. Whiskey, $\mathfrak{J}$ ss. q. 4 hours.

September 25th.—Convallaria, $\mathfrak{M}$ xv. four times a day. Bronchial breathing and voice now heard over region of dulness.

September 26th.—Patient very sick; cheeks dusky red; eyes bright, though sunken; chest full of coarse rattles; does not raise much: sputa yellowish. Whiskey, $\mathfrak{J}$ ss. q. 2 hours.

September 27th.—Pulse rapid and weak; at 4 A.M. flickering. Sputa rusty.

September 28th.—Convallaria, $\mathfrak{M}$ xv. q. 4 hours.

September 29th.—Delirious last night, got out of bed.

September 30th.—Again delirious during the night. Tongue pasty. Quiet this morning. Pulse a little stronger.

October 1st.—Pulse slower and stronger.

October 5th.—Temperature normal since September 29th. Convallaria stopped.

September 6th.—Whiskey, $\mathfrak{J}$ ss. four times a day.

September 22d.—Patient allowed to sit up. Crepitant friction râles over right base, found by Dr. Delafield yesterday. Physical signs otherwise normal.

November 2d.—Discharged cured.

Urine could be only imperfectly determined, as patient passed much of it involuntarily, but the convallaria did not seem to increase the amount.

DATE.	Pulse.	Respirations.	Temperature.
September 24th, A.M.	—	32	102.5°
September 24th, P.M.	148	32	101.8°
September 25th, A.M. (Convallaria, $\mathfrak{M}$ xv. four times daily)	120	28	102.5°
September 25th, P.M.	136	28	101.5°
September 26th, A.M.	132	30	102.9°
September 26th, P.M.	152	29	102.5°
September 27th, A.M.	148	32	102.3°
September 27th, P.M.	148	30	100.3°
September 28th, A.M.	140	30	101.8°
September 28th, P.M.	116	31	102.2°
September 29th, A.M. (Convallaria, $\mathfrak{M}$ xv. q. 4 hrs.)	132	26	101.2°
September 29th, P.M.	118	22	97.5°
September 30th, A.M.	132	30	99.1°
September 30th, P.M.	136	28	99.6°

After this temperature never reached 100°. Pulse remains over 100° as long as taken, *i.e.*, till October 13th.

CASE XIII.—*Lobar pneumonia*.—A woman, aged sixty-five, was brought into the hospital November 13th, having been sick two days. Patient hardly able to speak; rattles in throat. There was dulness and bronchial breathing at right apex; back of chest not examined on account of weakness of patient. Put on whiskey, $\mathfrak{J}$ ss. q. h.; convallaria, $\mathfrak{M}$ iij. q. h. Pulse was stronger November 13th P.M. but weaker again the next morning. Patient died November 14th, 3.20 P.M.

Autopsy, November 15th, showed complete consolidation of right lung in gray stage.

DATE.	Pulse.	Respirations.	Temperature.
November 13th, A.M.	144	34	101.6°
November 13th, P.M.	120	38	102.8°
November 14th, A.M.	144 (?)	40	101.8°

CASES XIV.—XVIII.—*Typhoid fever*.—In five cases of heart failure from typhoid fever, convallaria (with whiskey) was tried. It was usually run up to $\mathfrak{M}$ iv. q. h. or $\mathfrak{M}$ ij. q. $\frac{1}{2}$ h. It was sometimes thought that the pulse improved somewhat after the administration of the drug. The patients all died in one to three days, except the first, where the heart failure was due to intestinal hemorrhage. She recovered.

CASE XIX.—*Emphysema and chronic bronchitis*.—Convallaria ($\mathfrak{M}$ x. q. 4 h.) was given to a man with emphysema and bronchitis, increased in a week to $\mathfrak{M}$ xx. q. 4 h. Urine was quite constantly about thirty ounces daily, and was not increased by the convallaria. The pulse was not slowed. General condition rather improved.

CASE XX.—*Emphysema, chronic bronchitis, asthma*.—In a case of spasmodic asthma with emphysema, where nearly everything had been tried without avail to diminish the frequency of the attacks, convallaria, $\mathfrak{M}$ x. q. 4 h. and afterward the one per cent. solution of nitro-glycerine, $\mathfrak{M}$ j. t.i.d., if anything, aggravated the attacks.

Giving a short summary of the foregoing results I

should say that of the six cases of renal disease treated with convallaria, three (I., II., IV.) improved decidedly while taking the drug, and in three (III., V., VI.) little benefit could be observed. Case III. developed uræmic convulsions while on the drug. Case V., complicated with phthisis, was not affected, and Case VI. was very desperate from the start.

Of the five cases of cardiac disease four improved, one (XI.) very markedly (after digitalis had failed). Case VIII. improved at first but afterward got very much worse and recovered on digitalis. Case IX. was hopeless.

Case XII., of lobar pneumonia in an old woman, where the prognosis seemed very bad, did well. Case XIII. was nearly moribund on entrance and died.

Of the five cases of typhoid fever four died, and it is hard to say whether the convallaria had any good effect or not on them or in the one (XIV.) that recovered.

In the two cases of bronchitis and emphysema the results were doubtful.

If it be urged that this showing is not very favorable numerically, let it be remembered that the tests were very severe ones and in not a few of the cases convallaria was tried only as a last resort in cases hopeless from the start. Nearly all the cases were very serious, much more so than private practice would afford in such proportion. I feel certain that the results were at least as good as they are with digitalis in similar cases. Case XI. was as brilliant an example of the benefit to be derived from drugs in certain instances as I saw during my hospital experience. Cases I., II., IV., and XII. were very satisfactory, though it is very hard to distinguish the post from the propter. I feel sure that the rest in bed and proper diet afforded by the hospital will slow the pulse, increase the urine, and effect a remarkable change for the better in the patient's general condition in certain cases of cardiac and renal trouble, especially with dropsy, without the use of any drug whatever. I have seen such cases. I think the benefit in Case X., and perhaps in others, may be mainly attributed to rest and diet.

The pulse was markedly slowed in Cases I., VII., X. (?), and XI.; in the latter it could scarcely have been due to any cause other than the influence of the drug. The urine was markedly increased in Cases I., II., and IV., and in the last case we may fairly, I think, give the drug the credit.

The discovery of another heart tonic, which shall be on the whole as satisfactory as digitalis, and shall succeed in some instances, where digitalis fails, would be a great boon to the profession and to a most distressing class of sufferers. I think I have shown that we possess in convallaria such a drug. At least it merits further trial.

GERMAN MEDICAL STATISTICS.—The recent issue of the German *Reichs Medicinal Kalender*, contains some interesting statistical data. In the whole German Empire there are 17,623 regular practising physicians. Of this number Prussia has 8,634; Saxony, 1,017; Bavaria, 3,860; Wurtemberg, 1,053; Baden, 576; the remainder being distributed among the smaller provinces. The city of Berlin has but 1,048 physicians, which figures represent a proportion of 9.33 to 10,000 inhabitants. For the whole empire this proportion amounts to only 3.87, showing a tendency of the profession to flock to the centres of civilization.

Germany has 4,030 licensed pharmacies, of which number, 2,396 belong to Prussia. There are 238 county societies, and 68 purely scientific associations. 153 medical publications are issued from German presses, in addition to which there are 95 periodicals published by various medical societies.

PREVENTION OF HYDROPHOBIA.—Pasteur claims to have four dogs which cannot be inoculated with rabies by any method. These dogs have been protected by previous mild attacks of rabies, from which they recovered.

EXPERIMENTS IN PERITONEAL TRANSFUSION.¹

By JOSEPH W. HOWE, M.D.,

PROFESSOR OF CLINICAL SURGERY IN BELLEVUE HOSPITAL MEDICAL COLLEGE,
NEW YORK.

THE injection of blood into the peritoneal cavity was first recommended by Ponfick as a substitute for intravenous transfusion. He advised it in all cases of impending death from hemorrhage, or disease. Subsequently Bezzozero, Kachozorowski, and Golgi a Raggi published the results of their experiments. These were confirmatory of the success of the operation, and it was again recommended in cases of "pernicious anæmia, and to stimulate or encourage blood-making in all low states of the system." A brief *résumé* of these cases, in addition to my own experiments on dogs, will be of assistance in determining the status of peritoneal transfusion as compared with the injection of blood into its natural channels, the blood-vessels.

In making his experiments on animals Ponfick injected from one to two hundred grammes of blood, defibrinated and undefibrinated. At the end of twenty-four hours he found that the injected blood had been absorbed, and only a reddish film remained on the peritoneal covering of the intestines to show that peritoneal transfusion had been performed.

His first operation on the human adult was performed on a woman, thirty-one years of age, with phlegmonous inflammation of the upper extremity, accompanied with great anæmia. A slight rise in the temperature followed the operation, but no signs of peritoneal inflammation were discernible. She recovered in a short period after the injection. There seems to be nothing in the history of this case to show that transfusion of blood was indicated, or that ordinary means of medication, with nutritious diet, would not have accomplished the desired result.

The second case was one of chronic anæmia with paralysis. The patient survived the operation eighteen months. A post-mortem examination showed nothing abnormal in the abdominal cavity.

Kachozorowski reported five successful cases. His first case was one denominated "Puerperal-Venous Septicæmia." The patient had a miscarriage at the end of three months, followed by albuminuria, pleuro-pneumonia, and septic poisoning. From the combined effect of these diseases she became excessively exhausted, and her temperature went up to 103° F. (not much of a temperature for such a combination of serious disorders). Four weeks subsequently five hundred grammes of defibrinated blood were injected into the peritoneal cavity. The temperature went down one degree after the operation, and the general condition was improved. The injection was repeated in a few days, and was followed by much pain and redness at the seat of puncture. No other unpleasant symptoms followed the operation. The patient was discharged cured ten weeks from the day of her delivery.

The second case was one of chronic anæmia and hysteria, from masturbation. Four hundred and fifty grammes of defibrinated blood were injected. No inflammatory symptoms followed. Tonics were administered after the transfusion. Five weeks afterward the patient was discharged cured. This also seems to have been a case in which no operation was necessary.

The third case, a female patient in the third stage of phthisis, suffering from night-sweats and distressing cough, was treated by an injection of two hundred grammes of blood. On the third day following the operation the cough diminished, the appetite improved, and she became much stronger. Death took place at the end of three months.

The fourth case a sufferer from fungous degeneration of the cervix, capillary bronchitis, and exhaustion.

¹ Abstract of paper read before the New York Surgical Society.

He received an injection of six hundred grammes of blood. Nausea, vomiting, and local pain and tenderness followed the operation. At the end of the week the patient was able to leave her bed, and in three months was entirely cured.

The fifth case, a female suffering from typhus fever, had five hundred grammes of blood injected. A rapid amelioration of all the symptoms followed, and she was discharged cured soon after.

Golgi a Raggi also reports a successful case of peritoneal transfusion. The patient was an anæmic lunatic. He injected three hundred and ten cubic centimetres of blood defibrinated. The insanity and anæmia both disappeared, and a complete cure resulted. An examination of the blood of the patient by means of the "citometer," fourteen days after the operation, showed that the hemaglobine had increased from 35.8 to 57.9.

My experiments upon dogs were made with the purpose of ascertaining: 1, whether the peritoneum was capable of absorbing sufficient blood, in a period of time, that would benefit a patient at the point of death from great loss of blood or chronic anæmia, without exciting peritonitis. The question of time involved in absorption is of the utmost importance in determining the utility of the operation. Ponfick did not settle that question by his experiments, because he allowed the animals to live twenty-four hours before ascertaining what had become of the injected blood. If the animals had been killed within three or four hours after the operation, that point might have been settled; 2, I wished to determine whether other restorative liquids, such as milk, beef-tea, etc., would be tolerated and absorbed by the peritoneum as well as blood.

No. 1.—A dog weighing thirty-five pounds, well nourished and active, was etherized until all active movements had ceased. The cylinder of Dieulafoy's aspirator was charged with eight ounces of warm milk at 96° F. The hollow needle attached to the tube of exit was passed through the abdominal walls below and to the left of the umbilicus, then by turning the handle of the aspirator slowly the milk was injected. The operation was succeeded by a series of clonic spasms, very violent in character, which lasted about half a minute. Six hours later the dog was killed, and a post-mortem examination made by Dr. Collyer, house-surgeon of Charity Hospital. The abdominal cavity contained ten ounces of liquid, consisting of the milk previously injected, and a bloody serum, which gave the whole liquid a reddish tinge. The peritoneum was injected in patches near the seat of puncture. The other organs were normal.

No. 2.—A larger dog than the preceding, but not so well nourished, was etherized, and five ounces of warm milk were injected into the peritoneal cavity, by means of the aspirator. No unfavorable symptoms developed during or after the operation. The animal was kept under observation for four weeks, without exhibiting any signs of inflammation. So far as I know, the animal may yet be alive.

No. 3.—A large powerful slut in an advanced state of pregnancy was anesthetized, and eight ounces of nutritious liquid, consisting of equal parts of warm milk and bouillon, were injected in the same manner as before. At the end of five hours the dog was killed. Sixteen ounces of liquid, containing milk, beef-tea, and bloody serum, were found in the abdomen. The peritoneum was congested throughout.

No. 4.—This animal was operated upon at the same time. Seven ounces of warm water were injected into the peritoneum. Six hours afterward the animal was killed, and six ounces of a reddish brown liquid found in the cavity. The peritoneum was much more congested than in any of the preceding cases. The kidneys were congested, and a few ecchymotic spots were found underneath the capsule.

No. 5.—A large muscular dog was etherized, and two loose ligatures placed around the femoral artery. The

vessel was then cut between the ligatures, and allowed to bleed freely. When thirty ounces of blood had been collected, the ligatures were tightened, and the artery closed. A two-ounce solution of carbonate of ammonia, containing ten grains to the ounce, was added to seven ounces of the blood, and eight ounces of the mixture injected into as before. Two hours subsequently, the ligature slipped from the artery, and the dog bled to death. Eighteen hours afterward, a post-mortem examination was made by Dr. Collyer. Three ounces of bloody serum were found in the cavity. A thin reddish film covered a portion of the peritoneum. No lesions except those due to decomposition were found in other organs.

No. 6.—The femoral vein of this animal was ligated, and opened. Eight ounces of blood were collected and mixed as before with a solution of carbonate of ammonia. Seven ounces of the mixture were injected. Eight hours afterward, the dog was killed. Two ounces of liquid blood were found in the cavity. A reddish film covered the intestines as in the previous case.

No. 7.—Eight ounces of warm water were injected into the peritoneal cavity of this animal. When she had recovered from the ether, she gave evidences of pain by rolling around the floor and whining. In half an hour these symptoms subsided, and the dog remained comparatively quiet. Twenty hours after the operation a post-mortem was made. Fourteen ounces of a dusky colored liquid were found in the abdominal cavity. The peritoneum was injected throughout its whole extent. Small patches of lymph were also found, studding the membrane. There was no difference between the peritoneum at the point of injection and other parts.

No. 8.—Twelve ounces of blood were taken from the femoral vein, and the fibrin removed by whipping the blood with a glass rod, and afterward straining it through a piece of muslin. Five ounces were injected into the peritoneal cavity. Twenty-two hours later the dog was killed. No liquid was found, but the peritoneum was covered with a thick reddish coating, consisting probably of globular elements and coloring matter of the blood.

No. 9.—Eight ounces of defibrinated bullock's blood were injected into the abdomen of a very large and powerful dog. The animal seemed to be in great pain after the operation, and it did not seem to rally from the effects of the injection, as the other animals did. Eight hours subsequently a post-mortem was made, and four ounces of blood collected from the cavity. The same reddish coating of the intestines as in the preceding cases.

The foregoing experiments prove that the peritoneum will absorb blood, and consequently must assist in sustaining the functions of life; that the operation of peritoneal transfusion is liable to excite a limited amount of peritoneal inflammation; and if the blood of an animal of a different species from the one operated upon be used, there will be a likelihood of establishing general peritonitis. Even in intra-venous transfusion, much harm is likely to result from its use.

The injection of milk into the peritoneal cavity is of about as little benefit as when employed in intra-venous transfusion. A good result can rarely result from it. Whenever I have employed it in the human adult alarming symptoms were invariably produced by it, without any compensating improvement afterward, in the condition of the patient. The injection of the milk and bouillon, as well of milk alone, excited more or less peritonitis. The injection of plain water seems to have been followed by more irritation than any of the other liquids used. The explanation of this, I am unable to give. The fact, however, may throw some light on fatal cases of peritonitis, following operations in the abdomen where water was used freely for cleansing.

Granting the advocates of peritoneal transfusion that the peritoneum will absorb blood, and that the vital forces of the patient are sustained by it, I yet cannot see the utility of the operation. It is reasonable to suppose that organs such as the stomach and intestines,

specially designed by nature for purposes of absorption and nutrition, would take up nutritious liquid as fast, if not faster than the peritoneum, which, so far as we know, was not designed for such a use. It seems to me also, that any condition of the system which would prevent absorption by the stomach and intestines, would also prevent absorption by the peritoneum, or any other organ capable of performing that function. Indeed, there appears to be no valid reason for ignoring the stomach and intestines, unless these organs are the seat of serious disease. In such cases as those reported by Ponfick, Bezzozero, Kachzorowski, and others, the blood might as well have been injected into some portion of the intestinal tract as into the cavity of the peritoneum. In only one of these cases was any kind of transfusion indicated.

Whenever a patient is in danger of sudden death from great loss of blood, every moment lost diminishes the chances of recovery. Hence, it is not advisable to wait for either peritoneal or intestinal absorption. An immediate stimulation is necessary, and that can only be obtained by the injection into the veins of fresh blood from a healthy adult. Intra-venous transfusion is as easily performed as any other operation in surgery that I know of, and with a proper apparatus, and attention to the rules that I have frequently spoken of, there is little or no danger attending its performance.

TWO CASES OF ACUTE DIFFUSE MYELITIS, WITH AUTOPSIES.¹

By GEORGE L. PEABODY, M.D.,

VISITING PHYSICIAN TO BELLEVUE HOSPITAL; PATHOLOGIST TO THE NEW YORK HOSPITAL.

THE cases whose symptoms and lesions I am about to describe occurred under my care in the New York Hospital during the summer of 1881. I offer them, as being of interest by reason of the acuteness of the disease—one of the patients having lived seven days, the other only four, from the beginning of the attack—and because one of them presented certain unusual symptoms, which it is difficult to account for in view of the lesions in the cord, as I shall demonstrate them to you under the microscope.

Both of the patients were young, healthy, well-developed men, in whom no cause could be assigned for the disease, and in both it originated in the mid-dorsal region. In one of them it spread upward, involving all the elements of the cord as high as the third cervical nerve, where, by interference with the function of the phrenic nerve, it caused death from apnoea. In the other the tracheal plexus was very markedly interfered with, as well as the hypoglossal nerve, its nucleus in the medulla being, however, intact.

CASE I.—Albert Kummer, twenty-one years of age, from Germany, single, musician; admitted to the New York Hospital September 5, 1881, at 10 P.M. His family history is negative. He is a moderate drinker, chiefly of beer. Gives no traumatic history, and denies all venereal history, as well as all exposure to cold and wet. On getting up, three days and a half ago, at his usual hour in the morning, he first noticed a peculiar weakness in the legs, so pronounced that he could scarcely stand; also, that he could not fully extend the legs. His knees were tremulous, knocking together when he endeavored to stand, and he had severe frontal and occipital headache, and some vomiting. There was no chill and no vertigo, but he felt very feverish. The weakness in his legs grew steadily worse, and at night he was unable to stand at all. This was accompanied by a slight numbness, but no pain or formication was present either in his trunk or extremities. His appetite left him and his bowels became constipated, his sphincters remaining normal, and his bladder being under the control of his

will. A day or two later he began to experience similar weakness in his hands, especially the right, but had no dysaesthesia or paræsthesia in them.

On admission, at 10 P.M., his pulse was 108, his respiration 32, and his temperature 101.6°. He is large and well nourished, though slightly obese. There is no œdema. He is utterly unable to stand. He was given on the night of his admission ten grains of quinine and some citrate of magnesia.

That night he slept fairly. The next morning, September 6th, he was unable for the first time to pass water, and he was relieved by a catheter. There was no variation of importance in his pulse, respiration, or temperature. I first saw him at noon on this day. He was then perfectly intelligent, and complained only of headache and weakness in his legs. He lay upon his back, and was wholly unable to turn himself to his side or to sit up. He held his head somewhat drawn back, but said he was able to flex it without pain. There was no conjunctival injection; his pupils were equal and normal in all respects. His tongue was moist, flabby, and slightly coated. He was able to protrude it in the median line without difficulty. He lay with his legs partially flexed; and, on being asked to raise his feet from the bed, he made strong but ineffectual efforts to do so, partly flexing his thighs, and thus dragging his heels along the bed, but not raising them. He was able to move his toes freely and to rotate his legs, also very feebly to abduct and adduct them. He was then entirely unable to raise either hand to his head, but he was able feebly to flex his forearms and throw them over his chest by a motion from his shoulder. His fingers were flexed, and he was unable to extend them. The dynamometer showed great loss of power in both hands, as follows: Right hand, first trial, 15; second trial, 12. Left hand, first trial, 20; second trial, 30.

These measurements were on the large scale of the instrument. Tactile sensation was everywhere normal as tested by touching with hand, pin points, etc., and rubbing with hand, cloth, etc. The electro-muscular contractility remained good in the muscles of all his extremities in response both to the continuous and interrupted currents.

Direct palpation over the spinal column developed a point of tenderness between the scapulæ in the upper dorsal region. He also complained of a slight sense of pain in this situation when hot sponges were passed along the spinal column, but not upon similar application of cold sponges. I examined his abdominal and thoracic viscera with negative results. He was then put upon biniodide of mercury, gr. $\frac{1}{2}$, with potass. iodid., gr. x., t.i.d., and wet cups were applied along his spine sufficient to withdraw blood to the extent of ten ounces. His temperature rose steadily during the day, being at 6 P.M. 103.4°. No further symptoms developed on this the fifth day of his illness.

September 7th, 9.25 A.M.—Pulse, 104; respiration, 30; temperature, 102.2°. He slept poorly last night until midnight, at which time he received a dose of hydrate of chloral and bromide of potassium. A stimulating enema was followed by a free movement from the bowels, during which, as always before, the patient had no difficulty in controlling his sphincter. Urine is still drawn by catheter, and is normal in amount and in all other respects. His general condition, objective and subjective, has not materially changed. His loss of power is just as marked as yesterday, but apparently not more so. He still complains of severe frontal headache. There are no ocular symptoms. There is noticed, however, a slight difficulty in speech (which he is sure he never had before), consisting in a hesitation in pronouncing certain words, and an inability to pronounce them *distinctly* until he has repeated them *indistinctly* several times. His voice at times failing him and sinking to a whisper. Movements of the lips are unimpaired. During the day he had a normal, voluntary movement of the bowels, with

¹ Read before the New York Practitioners' Society, January 5, 1883.

normal control of his sphincter. His urine still has to be drawn. Various tests of sensation, power, etc., show the same results as yesterday, power being very defective, and sensory and tactile sensations being everywhere perfect. The point of tenderness over the spine is less distinct than it was. His temperature varied between 102.2° and 103.1° during the day. His pulse and respiration were a little quickened.

September 8th.—This morning there were no important changes in pulse, temperature, or respiration. Notwithstanding the administration of chloral again, with bromide of potassium, last evening, he passed a poor night. He is now able to pass water without the assistance of the catheter, and he controls his sphincters normally. This morning mercury and iodide of potassium are stopped, and he is given drachm doses of fluid extract of ergot. Muscular power in his extremities is unchanged since yesterday. Sensory and tactile perceptions are still normal. There are no ocular symptoms. Difficulty of speech has plainly increased. Enunciation is very labored and speech is thick. This is especially evident when he attempts to pronounce the linguals, he being unable to pronounce the letter "l" after many trials. Motion of his lips is perfect. He can whistle, etc. His mental condition is apparently good. Passed his urine voluntarily throughout the day, and retained control over his sphincters. His pulse, respiration, and temperature did not vary from their condition of yesterday. Early in the evening he fell asleep and slept quietly all night. At 5.25 A.M., on September 9th he was found dead.

Time from commencement of attack until death, exactly seven days.

As might be expected from this history, the lesions were localized chiefly in the anterior horns of the spinal cord. The autopsy was made six hours after death. All the organs except the cord were substantially normal. To the naked eye the only change noticeable in this was that the line of division between the white and gray matter was not as sharply drawn as it usually is in normal cords. I hardened it in Müller's fluid, and subsequently in alcohol, and have since examined sections from various parts of it. Throughout the entire cord there is a change in the blood-vessels which is very marked. They are everywhere full of blood, and surrounded by a coating of young cells, as by a sheath, these cells being disposed in several layers. This change is most marked in the gray matter of the dorsal and lumbar regions; but exists, also, as I have said above, in a modified way throughout the cord, except in the smallest vessels. The ganglion cells of the anterior horns are destroyed throughout the entire cord, and their places occupied by dense aggregations of young cells. Besides this, throughout the anterior horns there is a marked increase in the number of connective-tissue cells and free nuclei.

In the posterior horns the ganglion cells are well preserved; notably so in Clarke's columns. There is a slight increase in the number of connective-tissue cells and free nuclei in these horns, and the perivascularitis, as above described, is distinct in them. The white matter throughout is substantially normal, excepting the lesion of the blood-vessels.

In the medulla oblongata there are a few aggregations of young cells, but no such dense masses of them as were seen elsewhere. The olivary nucleus is normal in appearance, as is also the nucleus of the hypoglossus. The lesion of the blood-vessels is present, but is less well marked than it is below.

It is interesting, though not obscure, that there should have been interference with the function of the hypoglossal nerve so well marked, without any lesion of its nucleus, for here not even the lesion of the blood-vessels is present, though the capillaries are unduly filled with blood. It is somewhat surprising that the patient retained control of his sphincter ani. In concluding this case I beg to ask your attention to these diagrams illus-

trating the appearance of the gray matter of the anterior horns as compared with that of a normal cord, and also to the sections of the cord in various places, which are stained with carmine, and which I will place under the microscope for your inspection. I think you will agree with me that this case is one in which the chief lesions and symptoms are those of acute poliomyelitis anterior, notwithstanding the fact that death from that disease is said not to occur.

The second case was more acute, and the lesions more diffused. It is as follows:

CASE II.—J. W.—, aged twenty; United States; single; clerk. Admitted to the New York Hospital July 31, 1881. Family history is negative. He is a moderate drinker, and gives no specific history. He has had gonorrhœa once, but denies sexual excesses. One year ago he contracted malaria in New Jersey. He had measles last spring. He was in good health up to the beginning of this illness, which occurred two days ago. He has received no injury, and has not strained himself, or in any way exposed himself to cold or dampness. Two days ago he awoke with intense frontal headache. Soon after his left knee felt weak, and by night the entire lower limb on that side was powerless. He had no chill or pain. There were no other subjective symptoms at first. He had no paræsthesia or dysæsthesia, excepting a feeling of numbness over the left buttock and outer side of the left thigh. There was no girdle sensation or formication. On the following day the patient rapidly lost all power in the right leg, and was entirely unable to move either lower limb or his toes. He retained, however, perfect sensation in thighs, legs, and feet. Yesterday, the second day of illness, he vomited for the first time. His bowels were constipated from the beginning of the attack, and yesterday he was unable to void his urine. His sphincter ani has acted without impairment. On admission, 4.30 P.M., his temperature was 103.2° . The patient is intelligent, and gives a clear account of himself. He is well nourished, and complains chiefly of intense frontal headache, which has prevented him from sleeping ever since the attack began.

Heart and lungs are normal. Spleen and liver are normal in size. By percussion a distended bladder is detected, and thirty-five and a half ounces of urine are drawn by catheter. Both lower extremities are entirely paralyzed. The patient is utterly unable to move them. Sensation seems perfectly normal over both lower limbs, but all reflex action is gone. No tendon reflex at the knee. Patient readily distinguishes hot and cold objects applied to his lower extremities. There is no dysæsthesia or paræsthesia. There is no point of tenderness in the spine, either to pressure or to the application of hot and cold sponges alternately. Pupils are normal. There is no paralysis of tongue; no impediment of speech; no sense of constriction; no priapism.

Both legs are cool below the knee. Femoral and dorsalis pedis arteries on both sides can be felt.

The conjunctivæ are suffused. Respiration is quiet and natural.

August 1st.—Sixty-two ounces of urine were drawn by catheter at intervals during the night. Two enemata were given during the night without effect.

Yesterday, at 9.15 P.M., his temperature was 104.4° . This morning it is 103° ; respiration being 35, and pulse 84. His breath is foul. He has aphthous stomatitis. The cervical glands on the left side are somewhat enlarged. Pupils are normal, and there is slight internal strabismus of both eyes. The paralytic symptoms described yesterday are still present in the lower extremities, and are now rapidly appearing in the upper extremities. The patient has no motion in either arm, and very little in the fingers—the left side retaining more power than the right. Four hours after the above note (1.30 P.M.), the fingers were found to be completely paralyzed. The patient's sensorium is becoming dull; he gives contradictory answers to questions. His sen-

sation is still perfect, apparently; always (with closed eyes) he describes accurately any cutaneous irritation applied to arms, legs, or spine, such as heat, cold, pulling out hairs, inching and pricking—all which are carefully and repeatedly tried. On placing the poles of the galvanic battery (thirty-four cells) along the spine, and over the flexors and extensors of his arms and legs, no muscular contraction was obtained at any point (excepting over the flexors of the right hand) with either the continuous or the interrupted current. The application gave the patient the sensation as of a brush being passed over the skin, together with the sensation caused by the wet sponges.

At midnight the paralysis of all his limbs was complete, and his hands and feet were cold.

August 2d.—At 5.45 A.M. thoracic respiration ceased; the patient lies with his head thrown back, eyes staring and blood-shot, face extremely cyanotic, fingers cold and blue. There is internal strabismus of both eyes; the alæ nasi work forcibly; the tongue moves up and down with respiration, which is wholly diaphragmatic.

At 6.10 A.M. respiration ceased altogether, the heart beating several seconds longer.

His treatment was much the same as in the other case.

Time from commencement of attack until death, exactly four days.

I place under the microscope sections from the cord of this subject, taken at various heights. His other organs were substantially normal.

In this case the same vascular lesions exist as in the other, and are quite as general. The inflammatory lesions, including the destruction of ganglion cells, exist in the anterior horns, as in the other case throughout the cord, but are not confined to this situation. There is, moreover, a similar inflammatory destruction of the elements of the cord in the posterior horns. The ganglion cells of Clarke's columns are everywhere destroyed, and the posterior nerve-roots, as well as the rest of the gray matter, contain an increased number of young cells and free nuclei. Besides these changes there are lesions in the white matter in this case. Very generally the medullary sheaths and axis cylinders are broken down, forming together in some places granular, in others homogeneous masses. Near the periphery of the cord, especially in the posterior columns, but also elsewhere, may be seen many intact axis cylinders and nerve-fibres.

It is certainly worthy of note in this case that the sphincter ani was controlled, and that sensation was not abolished throughout his illness. I am aware that such cases are recorded, but I have not seen satisfactory explanation of them.

AN IMPROVEMENT IN THE ARRANGEMENT OF SNELLEN'S TEST-TYPES.

By A. SCHAPRINGER, M.D.,

ASSISTANT TO THE CHAIR OF OPHTHALMOLOGY AT THE NEW YORK POLYCLINIC.

In order to save time in the examination of eye-patients with Snellen's test-types, I have devised the following simple and inexpensive arrangement, which several of my colleagues have found to be serviceable. It consists of a screen made of a stout piece of paper or cardboard, a few inches wider than the sheet on which the test-types are printed, and twice as long, having an aperture in the middle just large enough to permit a single row of the types to be perceived through it. A cord is fastened to the upper and another to the lower end of the type-sheet. This is easily and effectually done by means of staples and suspension hooks, which can be had at any stationer's. The screen is tacked to the wall and the sheet placed behind it. Screw-eyes are introduced at suitable intervals into the wall, and the cords carried

through them to the place opposite the test-types, where the examining physician and the patient are placed. Two wooden handles attached to the ends of the cords afford a convenient means of grasping. When one handle is pulled down the other goes up, and one row of test-types after the other will appear in the aperture of the screen. The last screw-eyes through which the cords pass are arranged so that the handles will strike against them when the highest and lowest rows of type appear in the aperture, thus preventing the sheet from being pulled too far either way.

The height of the aperture in the screen is about three inches, and its width corresponds to that of the type-sheet. The type marked CC has been cut off and pasted in front of the screen, as it is too large to be seen entire through the opening. This, of course, need not be done when we have a sheet on which there is sufficient space between the rows so that the opening in the screen can be made larger.

Instead of cutting a piece from the middle of the paper screen, it will be found a little more practicable to make only two horizontal slits, about three inches apart and long enough to allow the type-sheet to be passed through them in such a way that the strip between the slits will, as it were, ride on the back of the sheet.

A screen like the one described can be seen in working order at the New York Polyclinic, where I put it up myself at the expense of a few cents only.

248 EAST SIXTY-FIRST STREET, January 10, 1883.

Progress of Medical Science.

PUNCTURE OF THE GRAVID UTERUS DURING OVARIOTOMY.—At a recent meeting of the New York Obstetrical Society, Dr. C. C. Lee related the following case. (*New York Medical Journal*, January 27, 1883). A patient, twenty-eight years of age, was sent to the Woman's Hospital by Dr. Hanks, for the removal of an ovarian cyst situated on the right side. The presence of the cyst was supposed to have been the cause of several miscarriages, and, as the patient was then three months pregnant, it was thought likely to prove so again. After making the usual incision for ovariectomy, the exact relation of the tumor to the uterus was ascertained. In turning the patient on her side, preparatory to puncturing the cyst, the latter was let go, and, unknown to Dr. Lee, the uterus took its place, rolling up into the abdominal incision, and was punctured instead. A large trocar penetrated the body of the womb to a depth of about two inches, entering at a point about two inches below the fundus. No fluid escaped when the trocar was withdrawn. The uterine wound was sewed up with carbolized silk, the long pedicle of the ovarian cyst was then ligated, the cyst was removed, and the abdominal wound was closed. Abortion had not occurred, and the patient was doing well. There had been vomiting, which was probably due to the influence of the anæsthetic. It was a noteworthy fact that the pedicle in this case was so long that the tumor, which was developed from the left ovary, lay upon the opposite side, in the region of the right ovary. Dr. Lee thought the silk-worm suture which was used to close the abdominal wound possessed no advantages over the carbolized-silk ligature. It was much more liable to break, and was less easy to handle.

FISTULA OF THE PANCREAS.—The following case is reported by Dr. D. Kulenkampf, in the *Berliner Klin. Wochenschrift*, No. 7, 1882, as an instance of pancreatic fistula. A laborer, thirty-nine years of age, received a severe injury, being hit on the abdomen. After the grave inflammatory symptoms had apparently subsided, he felt comparatively well, but still complained of gastric distress. Gradually a tumor developed in the epigastric region, and grew to about the size of a

child's head. As he was uncertain in regard to the diagnosis, Dr. Kulenkampff cut carefully through the abdominal wall, in the linea alba. Then he punctured the swelling and drew off about a wine-bottleful of clear fluid containing a large quantity of albumen. Later the peritoneum was attached to the abdominal walls, the tumor opened, and a quart of the same fluid taken out. He then established drainage, and daily several pints of this fluid were discharged. The wound closed, but a small fistula remained, and notwithstanding all endeavors, the skin surrounding it continued sore. This fact caused the suspicion that he had to do here with a pancreatic fistula, and the chemical analysis, which was made by the chemist, Dr. Hausmann, confirmed this. Nevertheless the fistula at length became permanently closed.

THE ADVANTAGES OF A DRY LOCAL TREATMENT IN OTORRHOEAL DISEASES.—One of the greatest hindrances to cure in an ear disease accompanied by otorrhœa, whether the disease be due to inflammation in the auditory canal or middle ear, is the presence of granulations and polypoid growths. Yet one of the oldest forms of treatment of otorrhœal disease has been by copious syringing and instillation of various fluid medicines. Hence, in such treatment of this class of aural diseases, moisture has been repeatedly applied to, and kept in the ear, a naturally heated locality. Now, as heat and moisture tend to promote granulations and keep up a discharge, it is very apparent that a moist treatment of otorrhœa in many instances has a tendency to keep up rather than to check the morbid discharge from the ear.

On these grounds, therefore, Dr. Chas. H. Burnett, in a paper with the above title, in the *American Journal of the Medical Sciences* for January, 1883, holds that the syringe and all forms of drops should be omitted from the home treatment by the patient in cases of otorrhœa. The most the patient should be directed to do is to dry his ear according to its need, by running into the canal and down to the fundus a twisted pencil of absorbent cotton. The surgeon is to use the syringe only when it is absolutely necessary to remove by it the matter from the ear, and thus prepare the organ for the application of medication by his hand. This latter part of the treatment should consist in the blowing of powders into the ear. Of these, Dr. Burnett recommends one prepared by triturating equal parts of tincture of *Calendula officinalis* with boracic acid (gr. to minim), allowing evaporation, then rubbing one part of the thus calendulated boracic acid with one or two parts of pure boracic acid. Alum should not be used, on account of its tendency to produce furuncles. Comparative tables are given, which show that by the dry method of treatment the average duration of treatment may be shortened from 212 days under the old plan, to 34 days by the dry method.

THE ANTISEPTIC AND PHYSIOLOGICAL ACTION OF RESORCIN.—From some experiments made by Dr. W. B. Platt (*American Journal of the Medical Sciences*, January, 1883), it appears, taking the minimum time in each series, that bacteria developed in 20 c.c. of urine exposed to favorable conditions, and that 0.050 gm. of resorcin has no appreciable influence, bacteria developing within eighteen hours.

Twice that quantity (0.103) kept urine free from bacteria twenty-four hours, six hours longer; while 0.150 deterred their development to four days, urine without any addition showing bacteria within eighteen hours.

If urine be boiled, organisms are found usually considerably later, forty-six to sixty-five hours.

0.050 gramme of carbolic acid hinders development of other living organisms (large enough to be detected by a power of 550 diameters) in boiled urine at least twelve days, bacteria eighteen days, the usual bacillus not developing at all. While 0.150 of resorcin (about two and a half grains) hinders development of bacteria four days, one-third that amount of carbolic acid pre-

serves a similar amount of urine free from organic life, under similar conditions, three times as long.

Experiments made to determine the physiological action of resorcin, showed that in several warm-blooded animals it caused—1. Restlessness and trembling. 2. Rapid respiration very early in rabbits. Early and very marked after a lethal dose in one dog, later after a lesser, but fatal dose, in another. Not marked after non-lethal doses. 3. Staggering, unsteady gait, loss of co-ordination, especially in hind limbs, present early in all the animals excepting one rabbit where a small dose was exhibited. 4. Twitching of muscles, especially of hind limbs, constant in all. 5. Clonic contraction of nearly all flexors and extensors of body, more especially of those attached to the pelvis and shoulder. 6. In the animals that died, the imitation of the natural running or hopping movements before death, as the animal lay upon its side, was striking.

BLENORRHOIC PLEURISY.—Several years ago Dr. Sée observed a case of gonorrhœal rheumatism, complicated by pleurisy. To his mind the pleurisy was evidently due to the venereal disease, since the two inflammations, arthritic and pleuritic, commenced at the same time and without any previous exposure on the part of the patient. Quite recently he saw another instance of this rare complication of gonorrhœa (*Journal de Médecine*, December, 1882). This was the case of a young man twenty-five years of age, who had contracted a gonorrhœa some three months previously. He was suddenly taken with chills, followed by pains in his side, fever and dyspnoea. Pressure upon the sides of the thorax induced the most acute pain. Upon his admission into the hospital, he showed evident signs of pleuritic effusion with extreme dyspnoea. He was not benefited by hypodermics of morphia. A hypodermic of nitrate of pilocarpine, however, gave an excellent result. Dr. Sée insists that the thoracic pain and the general instead of the local disorder is sufficient to establish a diagnosis of true gonorrhœal pleurisy.

STATISTICS OF SYMPHYSIOTOMY.—Dr. Robert P. Harris publishes in the *American Journal of the Medical Sciences* for January, 1883, a careful analysis of the statistics of symphysiotomy, with comparative tables of the early and later cases, showing that the operation has been more frequently performed in Italy in the last seventeen years than in the previous eighty. In his first table, extending up to 1858, out of 70 cases there was a maternal mortality of 70 per cent., and a fetal mortality of 67 per cent. The second table begins with the resuscitation of this operation in Naples, in 1866, and as far as he has been able to learn, there have been 53 operations in that city, saving 43 women and 42 children. From a report of Prof. Morisani, by whom most of these operations were performed, we learn that—1. All of the fifty operations (in table 2) were performed upon rachitic subjects, whose pelves were generally flattened antero-posteriorly. In four or five instances the pelves were simply dwarfed in dimensions. There was no case of rostrate pelvis, as malacosteon is very rarely met with in Naples. 2. Version was not resorted to except in the transverse positions. The forceps were applied in about one-fourth of the cases. 3. The separation at the pubes amounted to about 2 inches (50 mm.), which was obtained without any effort, and without producing any lesion of the sacro-iliac synchondroses. 4. The immovable dressing secured the firm union of the symphysis pubis in all the cases that recovered. 5. The women had good health after the operation. 6. There were no malformed infants. Nearly all of the children were sent to the Foundling Hospital to be taken care of. 7. Phlegmasia alba dolens did not occur in any of the women. 8. There were no pelvic lesions left, as a sequel of the operation, with the exception of one case of iliac phlegmon. 9. Vesico-vaginal fistula occurred in but one case, and this was easily cured by an operation.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, February 3, 1883.

WATER-SUPPLY OF NEW YORK CITY.

OUR editorial suggestions of the 20th ultimo, tending to arouse the citizens of New York City to make a searching inquiry into the true cause of the insufficiency of the water-supply, appears to have had the effect we aimed at. We pointed out that the trouble was not due to a defect in the quantity of water, but, on the contrary, to primitive and bad methods of distribution, which resulted in a waste of a large portion of the daily supply.

It is gratifying that our suggestions have been so ably handled by those who have interested themselves in this subject, and we find that the strongest evidence has been placed before the mayor's committee in support of our views. We stated that probably one-fourth of the water-supply of our city was wasted, but one witness observed that on some occasions fully half the supply of water to New York City was diverted from its legitimate use. Indeed, Mr. Henry J. Newton, of the Taxpayers' Central Committee, who has made a critical examination of the water-course, asserted that he found evidence that the water was run to waste systematically by the authorities in charge, who even retarded the flow in the aqueduct by artificial means, for the purpose of creating a pretended scarcity, and thus demonstrating an apparent necessity for another reservoir.

Commissioner Thompson denies this imputation, but appears to leave unanswered the facts produced by Mr. Newton, who states that he found a difference of depth of water between One Hundred and Thirty-fourth Street and Ninety-second Street, which could be explained only on the supposition that a waste of water existed between these points. We do not for a moment suppose that the escape-valves are fraudulently opened, but probably extensive leakages are permitted to exist, which have the same effect. Those who have allowed this systematic waste are the adherents of the political party which demands at this moment an expenditure of over fourteen million dollars for a new aqueduct. We apprehend that the most innocent of taxpayers will not fail to perceive the *raison d'être* of such behavior.

In regard to the individual waste of water by consumers, to which we directed special attention and suggested a remedy, Commissioner Thompson states that the introduction of meters into private houses would meet with "widespread opposition." In reply, we would observe that among a certain class the same "opposition," if likely to be successful, would be raised against

gas-meters, and possibly the inventor has too often received the anathema of the consumer when the monthly account was rendered.

The wasteful and prodigal consumers object to all methods of reckoning which fastens upon them the just payment for their extravagance; but the system of charging *pro rata* according to the amount used of anything, must certainly be based on a just and equitable principle, and be acceptable to all who have honest intentions.

The London system, however, to which we directed attention, does not provide for the use of meters in all private houses, but is merely optional to large consumers, such as hotels, manufactories, etc. We quite agree with Mr. Thompson that the universal use of meters would entail a troublesome and expensive system of inspection. The English plan of charging according to the number and size of cisterns in a house, has no such objection, as one assessment only is required, all future payments being the same, until additional cisterns are added.

As we stated, such a system appears to give satisfaction in England to consumers, and when combined with high pressure, insures a limitless supply to every part of the house.

It is admitted on all hands that the present amount of water at the command of New York City is sufficient for all purposes, provided the distribution is made by a system which insures against waste and extravagance. We have shown that the problem is not a difficult one, and have suggested a solution, which has at least the merit of being no novelty, as it is in practical operation in the largest city in the world. There it works with success, and meets the requirements of over three millions of people.

RESTORING THE POWERS OF THE NATIONAL BOARD OF HEALTH.

THE Senate "Select Committee to Investigate and Report the Best Means of Preventing the Introduction and Spread of Epidemic Diseases," to which was referred Senate Bill No. 2259, made its report on January 26, 1883, and the report has been ordered to be printed.

This bill (S. 2259) repeals the limiting clause of the act of June 2, 1879, entitled "An Act to Prevent the Introduction of Contagious or Infectious Diseases into the United States," better known as the "Quarantine Act," which expires by limitation on the 2d of June next. It also makes available the unexpended balance, previously appropriated, "of \$124,000, or so much thereof as may be necessary for carrying out the provisions of the several acts creating the board and defining its powers." It also makes available the appropriations heretofore made to enable the board "to aid State and local boards of health and local quarantine stations, to be used only in case of epidemic, the sum of \$100,000."

The report of the committee, recommending the passage of the bill, enters largely into the merits of the board, and claims that under its rules and regulations the yellow fever epidemic of 1879 "was actually stamped out in New Orleans and confined to the limits of Memphis."

The politico-legal aspect of the subject, "the power of Congress to regulate commerce in respect to the importation of contagion," is summed up in these words: "The powers of a State in respect to this question are based upon and limited by the law of self-preservation, and can go no farther than the protection of the people within its boundaries, while the power of Congress to regulate commerce is absolute, supreme, and exclusive." The report also says, "Our statute-books furnish a large number of precedents wherein Congress has, within the last fifty years, regulated commerce with no other object or purpose than to give greater security to the health and lives of that portion of our people who chance to be afloat upon our waters."

The report concludes with an appeal, a portion of which is here given: "When the memories of the fearful ravages of the epidemic of 1878 were fresh, both houses of Congress were ready to appropriate, and did appropriate all that the Committee asked for the purpose of endeavoring to find, if possible, a means of preventing the recurrence of this terrible scourge; but as the memories of the one hundred thousand sufferers, and the twenty thousand new-made graves of that period are fading from our minds, the Committee has experienced more or less difficulty in obtaining the appropriations necessary to enable the Board to perform the important duties which devolve upon it," etc.

Without entering upon the subject of the merits of the bill, we find that the report of the committee, where it treats of the politico-legal aspect of the subject of national quarantine is curiously at variance with the published opinion of the President of the National Board of Health. Thus the President in an exhaustive review of this whole subject, says: "To recapitulate, I hold that any attempt to supersede State authority in matters of quarantine, or for the general Government to exercise concurrent jurisdiction with the States in regard to quarantine, would be inexpedient for the following among other reasons:

"1. The decisions of the Supreme Court make it doubtful, to say the least, whether such powers are within the competence of the general Government.

"2. If the power be admitted, the exercise of it would be impolitic in view of the embittered opposition of the great commercial emporiums of the country.

"3. Such a system would almost necessarily lead to the establishment of an enormously expensive bureau, with no better means, probably, in respect to the protection of the public health, than can be realized, as experience has shown, by the system of co-operation with State and local boards."

In speaking of the Quarantine Act of 1878 (the Marine Hospital Service Act), the President of the National Board of Health says, in the review above spoken of: "The passage of the Quarantine Act in question was the single exception in the entire history of the Government to its otherwise consistent traditional policy, and this single exception seems to have been immediately repented of, for the very body in which the bill originated failed to make any provision for its execution."

From this it seems that there is a considerable difference of opinion as to the constitutionality of national quarantine even among its friends.

PERILS OF MEDICAL PRACTICE.

THE life of a physician is one of peril, as he encounters danger at every step of his existence. The portals of the contagious chamber which none dare enter are passed by him without a moment's hesitation; and fortunate is he who goes through life without disease directly incurred in his line of duty.

What is the reward? It is true that in some cases a well-earned competence is secured, but too often there is a weary struggle to secure the bare means of existence. There is, however, one danger which is ever present in the life of a physician which scarcely any prudence on his part can absolutely avert, bringing with it a train of horrors, to escape which death itself may be welcomed by a man of honor.

This peril is the accusation of female patients that attempts have been made on their chastity, when no cause for such a charge exists. The tragic conclusion to the most recent case of this description may well be remembered when future charges of this character are made against physicians bearing a spotless reputation.

Dr. William Whitfield Edwardes, of Hounslow, England, was the last victim to this system of blackmail. The unfortunate man naturally consulted his partner, a Dr. Whitmarsh, who, instead of trying to defend him as a friend, took the opportunity which offered of dissolving their business relations.

Finding himself assailed both from within and without, and possibly believing that he could not convince others of his innocence, when his own partner was ready to brand him as guilty, the wretched man "broke down," and by the aid of a bottle of prussic acid put an impassable barrier between himself and his persecutors.

Before death, poor Dr. Edwardes, so soon to stand before his Maker, solemnly and emphatically denied the charge brought against him, which he attributed to the "morbid imagination of a licentious-minded, hysterical woman," and "with a prayer for a blessing on his wife, his little boys, and his mother," concluded the document.

It is but little satisfaction for the loss of such a man to learn that the woman, struck with remorse, made a written retraction of the charge, with every expression of regret. All, however, that could be done for the bereaved relatives was performed, and a general expression of sympathy was displayed; the deceased was buried with military honors, the stores in the line of route to the tomb were closed, and crowds of sympathizing spectators lined the way.

It is said by our London correspondent that Dr. Whitmarsh's house was stoned by the mob, and the man would probably have been lynched if a body of forty mounted and other constables had not kept watch over the house for three days.

Dr. Edwardes is described as having been a hard-working physician, and distinguished in his profession; and although only resident in the district for twelve months, he had gained the esteem of all with whom he was brought in contact, by his devotion to his professional duties and attention to the poor.

Thus a valued life has been forfeited to the caprice of a woman, and we would ask how many more martyrs must be sacrificed before the medical man is protected in the discharge of his duties. The remedy is easily sug-

gested. Physicians should in all cases decline to make physical examinations of women except in the presence of a witness. This is not only a safe rule, but one easy to carry out even among the poorer classes. Any female who pretends to have too much modesty to allow the presence of a friendly attendant, should be looked upon with becoming suspicion.

CARDIAC SURGERY.

ONE of the latest developments of surgery relates to an organ which has for a long time been regarded as a *noli me tangere* by the operating surgeon. But now, a new era is beginning to dawn upon us, and the heart is to be duly admitted to the fraternity of organs that may be cut, sliced, and stitched with more or less impunity—more to the surgeon and generally somewhat less to the patient.

Punctures of the heart when conceived in moments of calmness, and executed with care and precision, are comparatively harmless. For, in 1872, Roger thrust a needle into the right ventricle of a child, and withdrew about six ounces of blood. There was no permanent mischief, and the patient died five months later from chronic heart disease. So also in Hulke's case ("Trans. Clin. Soc.," London, vol. viii.), a drachm of venous blood was taken from the heart, and the patient survived the withdrawal four weeks. Dr. John B. Roberts, of Philadelphia, is the fearless American apostle of the innocuousness of cardiac punctures. He also believes that cardiotomy, or at least cardicentesis, is preferable to phlebotomy in many threatening cases of distention of the heart.

Dr. C. L. Dana, however, in a letter printed in the present issue of THE MEDICAL RECORD, comes to a directly opposite conclusion.

Cloquet, Bouchut, Legros, and Onimus have also observed the apparent innocuousness of wounds of the heart made by capillary trocars. Steiner found, ten years or more ago, that electro-puncture needles could be quite safely introduced into either ventricle, provided they were at once withdrawn (*Med. Times and Gazette*, May, 1873).

It has been considered less safe to puncture the auricles; but the interesting paper of Dr. Benj. F. Westbrook, published in THE MEDICAL RECORD for December 23, 1882, would seem to show that our fears are as unfounded as were those of our predecessors in regard to ventricular puncture.

Dr. Westbrook's narrative has stimulated Dr. Roberts to further thought regarding cardiac surgery. He points out that if a few drachms of blood drawn directly from the heart give the relief that could only be afforded by taking a similar number of ounces from the veins of the arm, it seems proper to adopt the former measure. The subsequent circulatory depression from anæmia would undoubtedly be less than after the latter operation.

It is manifestly necessary, however, to determine that cardicentesis is innocuous before it can take the place of venesection. In Dr. Roberts' opinion the above-mentioned cases and Dr. Westbrook's experience tend to show that such is the fact.

Further experimentation in heart-puncture for the relief of cardiac distention and pulmonary engorgement seems, however, requisite. But Dr. Roberts thinks that

it will soon become a well-recognized surgical procedure in selected cases. He asserts that pericardicentesis has already taken that position, and there is no reason to believe that cardiac surgery will stop its march with the demonstration that the pericardium can be treated as the pleura.

Closely scrutinized, the results of cardiac operations have not hitherto been the most encouraging. There has been too much unanimity as regards the final fate of these cases. True, a similar unanimity of death has also been manifested by patients with excised or resected stomachs. But in extenuation it might be said that cancer kills painfully, often slowly, always surely. On the other hand, the gravest cardiac lesions may occasionally become fully compensated, and lead to comparatively comfortable existence. And again, death from heart disease is often quick and painless.

Far be it from us to deprecate the boldly progressive spirit of modern surgery. We owe too much to that tendency. But it does seem as if there were a limit somewhere, to proceed beyond which would be reckless and unjustifiable. Man is as yet incompletely evolved. Perfection still awaits him. In his present development the heart is emphatically a vital organ. And too much chiralurgical handling of that viscus seems as yet tolerably sure to be resented by the system.

QUAIL-EATING.

SOME men are born great and some attain greatness. Among these latter is the gentleman who is at date of writing attempting the interesting feat of eating sixty quails in thirty days. No doubt many medical men have been called upon to express professional opinion on the matter, and have properly beclouded the understandings of their listeners with glittering physiological generalities.

It is needless to moralize upon the foolishness of the performance or the silliness of the public in becoming excited over it. New York expends its brain-force in making money, and wants for its amusement things which make the slightest possible drain on mental tissues.

Quail-eating has become one of the excitements of the day, and it is proper enough for the doctor to say a word, since the matter involves a question of physiology. A brace of quails weighs, when dressed, rarely over three-fourths of a pound. In a normal diet it is permissible to eat even more than this amount of nitrogenous food. It is not a question of overfeeding, therefore, in the present instance, but of lack of variety in diet. The flesh of the quail is composed of solid muscular tissue, having no fat between the fibres as in the case of mammals. It is delicate and tender, and easily digestible, the process not taking over three hours. It is not strong-flavored, a quality which makes one soon tire of particular foods. There is no reason, therefore, why two quails a day cannot be eaten for a long time.

The highly scientific experiment now going on illustrates one interesting physiological fact. It is that after the system has assimilated a certain kind of food continuously for some time, the power of building tissue from it becomes weakened or lost. There is an analogy to this in other functions of the body. Thus in the case of the eye, particular rays of light, after continuously beat-

ing against the retinal expansion of the optic nerve, blunt the sensibility of the part which they excite. So the gustatory and olfactory senses soon fail to be consciously excited after uninterrupted irritations of the same kind. We have heard even that some of our city specialists can no longer smell iodoform.

MICROCOCCLUS PUERPERALIS.

RECENTLY pathological investigation has pointed very strongly toward the conclusion that a micro-organism is the cause of puerperal septicæmia. We are quite prepared, therefore, for the announcement that M. Chauveau has isolated this organism, cultivated it, attenuated it, and used the attenuation as a vaccine.

M. Chauveau experimented with rabbits, and states that he produced in them the lesions and symptoms of puerperal fever. His experiments as to the protective power of attenuated virus are not yet completed. But he states that those rabbits which survive the first inoculations are not susceptible to any subsequent attacks, even when virulent virus is injected.

The profession will wait with much interest for the conclusion of Chauveau's experiments.

SCHOOL HYGIENE IN OHIO.

A BILL has been introduced into the Legislature of the State of Ohio containing the following very excellent provision :

"The Board of Health [of corporate cities and towns] may take measures and supply agents, and afford inducements and facilities for gratuitous vaccination and disinfection, may afford medical relief to and among the poor of the corporation as, in its opinion, the protection of the public health may require ; and during the prevalence of any epidemic may provide temporary hospitals for such purposes (and the said board is hereby required to inspect semi-annually, and oftener if in the judgment of the board it shall be deemed necessary, the sanitary condition of all schools and school buildings within the limits of the corporation)."

The section goes as nearly as possible to compulsory vaccination without absolutely adopting it. It seems to us eminently wise and in accordance with what modern sanitary science demands. Such a provision, or a similar one, ought certainly to be adopted not only in Ohio but in other States.

PSYCHIATRICAL REFORM AND PSYCHIATRICAL TEACHING.

WE have regarded the agitation which has been made during the past few years over lunacy matters as one of the most important of recent scientific and humanitarian movements. This has been our excuse for so frequently urging the subject upon our readers. We take pleasure now in recording the marked success of the last meeting of the National Association for the Protection of the Insane, since this Society represents the movement in question. There seems little doubt now that the Association is placed upon a secure basis. Its membership has become large, the interest taken in its doings is widely extended, while the number and character of the men associated with it insures continued stability and

usefulness. It only remains for it to use wisely the position it has obtained. If this is done, continued improvement in lunacy matters in this country may fairly be expected.

Among the matters discussed at the recent annual meeting, the one of most immediate and general interest was that of teaching clinical psychiatry in our medical colleges. Without doubt this matter has been greatly neglected. Surely no one will deny that a medical student ought to see, at least, a few insane men, and know something about insanity before he graduates. Yet practically this subject is almost entirely ignored, and the young physician may be called upon to treat or commit the first lunatic he has ever professionally seen. We submit that such a state of affairs deserves some attention from our medical colleges.

News of the Week.

REGISTRATION OF PLUMBERS.—A bill providing for the registration of plumbers and supervision of plumbing work in Cincinnati has been introduced in the Ohio Legislature, at the instance of the Master Plumber Association of that city.

HOSPITAL SUNDAY IN BALTIMORE.—The collections of the Hospital Sunday, at Baltimore, amounted to about \$2,000.

DR. JOSEPH T. SMITH has resigned the Chair of Anatomy in the Baltimore Medical College. Dr. Thomas Dougherty has been appointed Lecturer on Physiology in the same institution, *vice* Dr. B. F. Leonard, resigned.

THE BALTIMORE MEDICAL STUDENTS number in the aggregate five hundred and ninety.

THE HEALTH OFFICER OF PHILADELPHIA, recently appointed, is Gen. James L. Selfridge. His chief qualification seems to be that he has been clerk in the State Assembly.

THE BALTIMORE MEDICAL ASSOCIATION, the oldest medical society of that city, recently held its seventeenth annual meeting, and elected Dr. J. S. Conrad, President.

RIOTOUS MEDICAL STUDENTS IN MONTREAL.—About three hundred medical students from the various universities in Montreal created considerable disturbance in that city, on the occasion of the recent trial of one of their number for body-snatching. Several of the rioters were arrested and bound over to keep the peace.

SMALL-POX IN BALTIMORE is decreasing. At last accounts only twenty new cases were reported as occurring in a day.

DUTY ON QUININE.—The Philadelphia Drug Exchange recommends the restoration of sulphate of quinine to the dutiable list.

THE DEATH OF MRS. BEARD.—Mrs. Elizabeth A. Beard, wife of the late Dr. George M. Beard, died of pneumonia at the Grand Hotel, New York, January 31st. Only last week her husband died of the same disease.

THE LETTSOMIAN LECTURES are being delivered this year by Dr. A. Ernest Sansom. The subject is "Endocarditis."

NAVY NEWS.—Surgeon J. R. Tryon and Surgeon Robert Whiting, detained from the Alaska and ordered home. Assistant-Surgeon C. W. Rush, ordered to the Naval Hospital, New York, *vice* P. A. Surgeon A. C. H. Russell, detached and ordered to the Navy Yard, Washington, D. C.

PLUMBING LAW FOR BOSTON.—The bill now before the Massachusetts Legislature in regard to the regulation and inspection of plumbing in the city of Boston, is a most excellent measure. Its provisions are very similar to those in force in this city. The supervision is to be in the hands of the Inspector of Buildings, and all work must be approved by him under penalty of heavy fines.

GOVERNOR BUTLER'S PROMISES.—The recent action of Governor Butler, of Massachusetts, in omitting Dr. Folsom's name from the list of those reappointed to the State Board of Health, Lunacy, and Charity, of which he has been a most useful member, and the only expert on insanity in the board, is not all that might be desired. No action has yet been taken on the matter by the Governor's Council. Several other appointments directly affecting the medical profession are to be made by Governor Butler. Among these are four State Trustees of the Massachusetts General Hospital.

HOW GAMBETTA LOST HIS EYE.—The following is the true history of the case, as given by our correspondent: When about eight years of age, he met with an accident in the right eye which wounded the cornea and which was followed by glaucomatous irido-choroiditis with protrusion of the eye. The eye remained for some time in this state, but the patient having been seized with intense pains in that organ, Dr. Fiensal, his personal friend and physician, fearing that the left eye would become affected by sympathy, consulted Dr. de Wecker, the well-known oculist, who removed the diseased eye in order to save the other. This happened in 1867, and the operation succeeded so well that none but those who were acquainted with the circumstance could imagine that the great French republican leader had lost an eye, as the false one he wore looked so natural in color, size, etc., and even the very movements in it were so normal that it was almost impossible to distinguish it from the healthy one.

THE AUTHORITIES OF TRINITY COLLEGE, ONTARIO, state that no offer was made to the seceding students of the Kingston Medical School, to take without extra fees such as had paid their dues; nor was any promise made to the remainder of said students to receive them for half-price. A statement to this effect is published in the last number of the *Canada Lancet*.

SURGEON-GENERAL OF MAINE.—Dr. Augustus C. Hamlin, of Bangor, who has lately been appointed Surgeon-General of Maine, on the Staff of Governor Robie, is one of the most distinguished medical officers in New England. He served in the army during the entire war. He was entrusted with important commands in the Army

of the Potomac, as Medical Director, and in the Army of West Virginia. He was afterward promoted to one of the highest positions, that of Medical Inspector, in the Staff of the Regular Army; and served with distinction in the Army of the South, during the famous siege of Fort Wagner, and was afterward assigned to the Armies of the Southwest, under the command of Major-General Thomas. Dr. Hamlin is a man of high scientific attainments, and is a member of numerous scientific societies, both at home and abroad. The militia of Maine are to be congratulated upon having so eminent an officer at the head of their Medical Staff.

SMALL-POX IN ATLANTA.—Dr. James B. Baird, Secretary of the Board of Health, of Atlanta, states that every possible care is taken to discover and quarantine cases of small-pox in that city. Vaccination is largely practised, and the transfer of small-pox cases to the pest-house is made with the utmost precautions against the spread of the disease.

INSTRUCTION TO DELEGATES.—At the last meeting of the Putnam County Medical Society, a resolution to instruct the delegates to the State Society was lost by a tie vote.

PROFESSOR HERMANN HELMHOLTZ.—The Emperor of Germany has raised Dr. Hermann Helmholtz, the eminent German physiologist, to the rank of a noble.

NO NEW CASES OF TYPHUS occurred in the city during the past week.

NEW YORK ACADEMY OF MEDICINE.—Dr. Fordyce Barker, the president of the Academy, after the transaction of the routine business of the meeting of February 1st, delivered an eloquent inaugural address. It contained fitting references to the past, and was ripe with suggestions concerning the future work of the Academy, over whose deliberations he has presided with such unanimous acceptance during the last two terms. At the close of the address, which was listened to with marked attention by a large and appreciative audience, the Fellows and guests were invited to attend a reception given by the president and vice-president, to Mr. F. Seymour Haden, of London, and to join in "the Loving Cup."

PROGRESS OF DIPLOMA MANUFACTURE IN MASSACHUSETTS.—Since the Bellevue Medical College of Massachusetts was exposed—and proved to be legal—the "American University of Boston," president Dr. Buchanan (familiar name in this connection), and the "First Medical College of the American Health Society," located at Boston, have been incorporated, and Dr. Alfred Booth, the first president and one of the incorporators of the "Boston Bellevue," has given notice of his intention to start the "Excelsior Medical College."

DOCTORS CHARGED WITH CONSPIRACY.—Dr. S. B. McDowell and Dr. Henry Beates, of Philadelphia, have been sued on a charge of conspiracy, to obtain from an aged and helpless invalid a conveyance or assignment of all her possessions, without any other consideration than the possible claim that McDowell might have set up for medical services rendered on two occasions. The physicians were held for trial at court.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Anniversary Meeting, January 10, 1883.

GEORGE L. PEABODY, M.D., VICE-PRESIDENT, IN THE CHAIR.

LIGATURE OF THE COMMON CAROTID ARTERY, AND REMOVAL OF A SARCOMA OF THE LOWER JAW.

DR. JOSEPH W. HOWE presented a specimen with the following history: "Fanny S—, forty-nine years of age, and a domestic, stated that she had enjoyed excellent health up to within two years ago. She then noticed a small tumor on the gum of the left side lower jaw. It was firm and inelastic, and for some time gave her little or no pain. Dr. Howe saw her first in May, 1882, when the tumor was about the size of a hen's egg, and occupied a portion of the ramus as well as the body of the jaw. The larger part of the mass was external and below the jaw. A portion of the floor of the mouth was also involved. She was advised to have it removed without delay, but she refused and returned to her home in the country. She returned during the latter part of September last, and was admitted to St. Francis' Hospital. The tumor had increased very much in every direction. It extended up to the roof of the pharynx, and laterally and posteriorly as far as the mastoid process of the temporal bone. It also involved the salivary glands in the floor of the mouth, and some of the muscles of the tongue. She was in constant pain, and could only obtain sleep by the use of large doses of morphia. After consultation with his colleagues, Drs. George F. Shrady and Joseph D. Bryant, it was determined to attempt the removal of the tumor.

On October 7th, assisted by Drs. Shrady and Bryant, the operation was performed. As a preliminary step in the procedure, the common carotid artery was ligated. This was done for two reasons, viz.: to diminish the growth of the tumor in case it was found impossible to remove the mass, and also to prevent severe hemorrhage during the dissection of the tumor. As the growth extended beyond the median line, the jaw was cut through about half an inch to the right of the symphysis, and severed from its attachments at the floor of the mouth. The tumor was then dissected from its attachments as far back as the pillars of the fauces, and removed, leaving a piece, including the condyle of the lower jaw, attached above. This was also removed. It was then seen that there were prolongations of the growth along the base of the skull, at the roof of the pharynx, and under the tongue as far as the opposite side of that organ, which it would not be advisable to remove. The patient rallied well from the operation. She was given fifteen minims of Magendie's solution of morphia, and passed a comparatively comfortable night. She partook of liquid food on Sunday, with little difficulty; her temperature was only 101° F., and her pulse 110. There was no sign of distress or special weakness. She wrote upon a slate for all she wanted. Shortly after dinner on Sunday she suddenly became hemiplegic on the right side. The pulse ran up to 135, but her temperature remained about as it was before the attack. The day following, the paralysis became more marked and the coma complete. The breathing was markedly stertorous, and her bowels were moved involuntarily. On October 11th these symptoms were intensified, without any increase in the temperature. She died comatose on the evening of the 11th. Her death was evidently due to the ligature of the carotid, and consequent anæmia of the brain."

REMOVAL OF RIGHT HALF OF INFERIOR MAXILLA THROUGH THE MOUTH—FORMATION OF NEW JAW IN TWO PIECES.

Dr. Howe also presented a lower jawbone, accompanied by the following history: "August B—, thirty-eight years of age; occupation, tailor; was admitted to

St. Francis' Hospital, August 5, 1882. Family history good. He never had syphilis or any other form of venereal disease. Twelve months ago he had diphtheria, which left him rather weak. Ten weeks previous to admission he was upset from a row-boat, and afterward suffered from severe pain in the jaw on the left side. This was accompanied by swelling all along the whole body of the jaw. On admission, extensive necrosis was found to exist as far back as the ramus. On September 10th, Dr. J. D. Bryant, who was on duty at the time, separated a large portion of the periosteum from the necrosed bone. The mouth was washed daily afterward with carbolyzed water, until October 11th, when Dr. Howe completed the separation of the periosteum, and removed the bone through the mouth, while the patient was under ether. A new ramus and a new body had by this time formed, but the two were not joined. This division of the new jaw caused the patient considerable trouble on account of the anterior fragment overlapping the posterior, and preventing the teeth of the lower jaw from approximating with the others during mastication. An external splint was applied to remedy this defect. It did little good, however, and he sent the patient to Dr. Goodwillie, who made an intra-oral splint, which he thought would remove the difficulty. I have not seen the patient since."

DR. GOODWILLIE, on invitation, remarked that three things were necessary to the proper reproduction of bone in the lower jaw: first, perfect rest, and in order to secure that it was necessary to apply an intra-oral splint which would hold the lower jaw in contact with the upper one. Second, there should be an extra-oral splint to support the new jaw in its place. Third, there should be careful dressing, and it was well to make a drainage opening through the extra-oral splint, so that all the secretions, even the mucus, could be thoroughly washed out. Thorough cleansing, rest, and support, both external and internal, were essential in the treatment of these cases. He thought the non-union in the specimen presented by Dr. Howe was explained by the fact that the muscles of the left side pulled the jaw around and allowed the periosteum to contract and heal without keeping the form of the jaw. It also seemed to him that the pterygoid muscles became contracted, as did all muscles when they were not in use, and in that way non-union was favored.

DR. HOWE remarked that in the specimen presented the fragments of bone were in contact, that the periosteum was stripped up to a distance for three or four inches before he operated; that he then stripped off the remaining portion of the periosteum, and he could not understand why the two pieces should not have united.

DR. GOODWILLIE thought the non-union was due in this instance to movement, and that if there had been perfect immobility union probably would have taken place.

DR. HOWE suggested that the destruction of periosteum upon the outside and inside perhaps prevented union.

DR. GOODWILLIE was of opinion that sufficient periosteum existed to permit union, but that movements of the fragments prevented it from taking place.

NEURO-FIBROMA.

DR. RIPLEY presented a specimen accompanied by the following history:

"Last July he saw, with Dr. George Schlereth, Mrs. B—, a vigorous woman, twenty-nine years old, who had been married eleven years. She was the mother of three children, the eldest of whom was ten years of age, and she was then in the third month of pregnancy with her fourth child. Nine years ago she began to suffer from intermittent pains, which radiated from the internal portion of her left leg just below the knee. On examination, she discovered a small, painful nodule at the point from which the pain proceeded. These pains, often excruciating, were much increased in severity by mental excitement at her

menstrual periods and during pregnancy. They were also worse at night. From year to year, too, they had been gradually becoming more continuous. During the three weeks preceding the time that Dr. Ripley saw her she had had little relief, night or day, and said the affected part felt as though it were being pierced with a hot iron. This was the history of her case, and on examination he found a hard, painful subcutaneous tumor, apparently about the size of a peanut kernel, situated three inches below the head of the left tibia, on the inner aspect of the leg. It was surrounded by a small area of thickened integument, to which it was attached, and the whole mass was slightly movable.

Dr. Schlereth had already expressed the opinion that the growth was what is generally known as a neurofibroma and that it should be removed; an opinion in which Dr. Ripley fully concurred. A few days later, at the doctor's request and with his assistance, he extirpated the tumor, removing also the thickened integument with it. The wound healed rapidly and without suppuration, and from that time to the present there has been no return of the pain. On section, in gross appearance, the tumor was found to be a solid, nearly globular body, about the size of a large pea, of a yellowish color in its periphery, but nearly white in the centre. Under the microscope, after hardening in alcohol and staining with osmic acid, it appeared to be made up for the most part of bundles of fibrous tissues crossing one another in different directions. A few non-medullated nerves were seen, and here and there, a blood-vessel with thickened wall. Drs. Heitzman and Wendt have both examined specimens from the tumor, and the former thinks that they contain a few smooth muscle fibres.

Remarks.—The clinical history of this case seemed to me to be of interest in showing how a small and structurally unimportant morbid growth, encroaching upon no vital or sensitive organ, may give rise to years of the most intense suffering. The marked effect which deviations from a normal condition of mind or body had in increasing the severity of the pain, was also an instructive feature in the case. In 1812 William Wood published in the *Edinburgh Medical and Surgical Journal* two articles on these little tumors, in which he gave a detailed history of a number of cases, several of them occurring in his own practice. The symptomatology of one of them, quoted from Pearson, is quite like mine. He states that they occur more frequently in females, and also are more common in the extremities. Of the five cases seen by me, three were in the female breast, one in the male breast, and the other in the extremity. In the male referred to, the tumor was situated in the left breast, and the disease simulated angina pectoris, for which it was for a long time mistaken. The paroxysms of pain were very severe, resulting during one seizure in syncope and complete loss of consciousness.

In neither of those seen by him was the skin affected, differing in that respect from mine. Although these tumors have been so long recognized, authors differ as to their structure. Lockhart Clarke says they have a fibrous or fibro-cartilaginous structure. Paget thinks the pain depends on neither their locality nor their structure, for in some situations he has found fibro-cartilaginous and fatty tumors similarly painful, also mammary glandular tumors, but we believe they are most frequently subcutaneous and fibrous, or fibro-cellular. Cornil and Ranvier class them with neuromata, and say that they probably contain nerves which are compressed by the new connective tissue."

URETHRAL CALCULI.

DR. WYETH presented several specimens of urethral calculi, which he had removed from a man forty-five years of age, who came under his observation at the polyclinic. The man had one stricture five inches from the meatus, and one below this, through which a small French bougie—eight or ten—passed quite readily and

struck the calculi. After some ineffectual efforts to remove them by means of forceps, he introduced Bank's instrument and performed internal urethrotomy, dividing both strictures, after which he was able to remove the four small calculi. Behind all of them was a fifth one, for the removal of which he performed urethral lithotomy by means of strong forceps.

Dr. Wyeth also presented a microscopical section, which illustrated the lesions of

SYPHILITIC ENDARTERITIS.

The proliferation had taken place between the different layers of normal intima. The specimen was removed from the body of a patient who had had tertiary symptoms for many years. She had been hemiplegic for fifteen years, and died two or three weeks ago suddenly. At the autopsy this condition of the walls of the basilar artery was found near its bifurcation. There was also a gummatous tumor in the medulla oblongata. The chief point of interest in the specimen was that, six or seven years ago, he attended, with Dr. Weber, a patient who had tertiary syphilis, and who died quite suddenly, the manner of death being about the same as in the case from which the specimen presented was taken. In Dr. Weber's case there was also complete occlusion of the basilar artery, and the conclusion was reached that the patient died in consequence of anæmia of the medulla, induced by the obstructed condition of the blood-vessel. In the present case he predicted that obliterating endarteritis of the basilar artery would be found, and the microscopical specimen showed the pathological condition.

Dr. Wyeth also presented a microscopical section which illustrated

TRAUMATIC ENDARTERITIS.

It was taken from the carotid of a horse which he had tied with the sciatic nerve of the calf. On examining the artery he found a slight bulging inward of the intima, but there was no true proliferation of the internal coat, and no other change had taken place in the arterial walls. The morbid changes present were those which indicated the existence of endarteritis, and in this case it was of traumatic origin.

DR. PEABODY remarked that it had occurred to him in quite a number of instances to find this form of arteritis obliterans, but he had in the majority of instances found it in subjects who were not syphilitic. The lesion had always been attended by the same microscopical appearances which had been described by Dr. Wyeth. It had first been described by Heubner as syphilitic arteritis of the brain, but it had been found to exist in other parts of the body. Dr. Peabody had found it in the kidneys, with chronic Bright's disease, and in chronic disease of the lungs. In two cases he had found it with malignant tumor of the tongue and antrum.

DR. RIPLEY said that at the Medical and Surgical Society Dr. Delafield recently reported a case and made the positive statement that the lesion was not necessarily of syphilitic origin.

DR. WYETH further remarked that the condition had been described at length by Greenfield, Gowers, Buzzard, and many other London pathologists, in volume twenty-eight of the "Transactions of the London Pathological Society," and in all those cases the syphilitic lesions had figured more or less completely.

Dr. Wyeth, however, was of the opinion that any disease which involved the peri-vascular space might give rise to a condition which would cause endarteritis, no matter whether it was syphilitic or tuberculous in character.

DR. BIRDSALL had become convinced that the view expressed by the Vice-President, that it was not always easy to distinguish between the syphilitic and other cases, was gradually gaining ground.

DR. WYETH believed the second microscopical section which he presented proved that an endarteritis sufficient

to occlude the vessel could be caused by simply bringing the surface of the intima closely in contact.

DR. HOWE remarked that he had already presented a patient to the Society upon whom he had operated for popliteal aneurism, who illustrated the point referred to by Dr. Wyeth. Only sufficient pressure was made with the ligature to bring the inner walls of the artery into close coaptation and the operation was successful.

The Society then went into executive session.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, January 5, 1883.

JAMES B. HUNTER, M.D., PRESIDENT, IN THE CHAIR.

THE paper of the evening was read by DR. GEORGE L. PEABODY, and was entitled,

CASES OF ACUTE DIFFUSE MYELITIS.

[The paper is printed in full on page 122.]

DR. BEVERLEY ROBINSON presented a case of

ASTHMA DEPENDENT UPON VESICULAR EMPHYSEMA, RELIEVED IN A REMARKABLE DEGREE BY THE INTERNAL USE OF THE FLUID EXTRACT OF THE ROOT OF CONVALLARIA MAIALIS.

The history was as follows: J. H.—, aged sixty three, German, came to the Out-Door Department of the New York Hospital, October 4, 1882. He complained of constant dyspnoea and sleepless nights. He was poorly nourished, and his nose and lips were cyanosed. His health was tolerably good until eleven years ago, when he began to suffer from shortness of breath on exertion. At present, even the slight effort of putting on his shirt exhausts him.

His mother and two of his brothers were affected in the same manner. His voice is short and jerky, and he occasionally spits a small quantity of thick, gluey sputum, preceded by a cough of moderate intensity.

The expectoration of this substance relieves his dyspnoea somewhat, for a time. His appetite is poor, his bowels obstinately constipated. He is compelled at night to assume a semi-recumbent posture in order to obtain any sleep at all.

Physical examination of the lungs reveals great emaciation of the chest-walls; shoulders high; back much bent over; thorax dilated at the base; sterno-mastoid, scaleni, and trapezius muscles are prominent during inspiration; chest moves as a whole in a vertical direction during the respiratory acts; third and lower intercostal spaces are sucked in visibly with each effort to breathe. Alæ of nose are markedly distended; expiration is stertorous. Superficial veins of arms and forearms are much dilated. There is considerable pulsation of the brachial arteries at the elbows. On percussion hyper-resonance covering a wide area is discovered, which is especially pronounced on the left side of the thorax. Auscultation anteriorly gives rough inspiration with numerous sonorous rhonchi on both sides; expiratory sounds are feeble. Posteriorly, inspiratory vesicular murmur is very feeble; expiratory sounds are loud, and accompanied with disseminated dry râles.

Physical examination of heart shows apex-beat in fifth intercostal space to left of nipple; epigastric pulsation diffused; cardiac beats are but feebly felt; arteromatous changes in arteries are at an advanced stage. There is a faint blowing murmur synchronous with the systole, and heard with greatest intensity outside and somewhat below the left nipple.

Patient's symptoms always become more accentuated toward evening. Atmospheric changes have no obvious influence upon their character or degree. Country air in past time has apparently given him relief from his continued oppression. Several years ago, while in Rock-

land County, he felt much better than usual. At present he is prevented from leaving the city on account of his narrow means. Latterly he has taken medicine sparingly; in former years he took large quantities of different kinds of medicine. Spirit of camphor, in 20 gtt. doses, formerly gave him great temporary relief. He is now very much annoyed by a condition of cutaneous irritation, which has occasioned prurigo to an excessive degree.

October 4, 1882.—At 3.50 P.M. fl. extr. convallaria $\mathfrak{M}$ xv. were given by the mouth. Twenty minutes later patient states that he breathes with much greater ease, notwithstanding a rapid walk of several minutes' duration through the waiting-room of the hospital.

R. Fl. extr. convallariæ $\mathfrak{M}$ iv.

Syrupi tolutani $\mathfrak{M}$ viij.

Aquam q. s. ad. $\mathfrak{z}$ j.

M.—S. To be taken by the mouth every three hours. October.—Fl. extr. convallariæ gtt. v.

S. Take every three hours.

October 16th.—Medicine seems to benefit him, inasmuch as he continues to breathe with greater comfort to himself.

October 20th.—*Statu quo*—continue treatment.

October 27th.—Repeat treatment

November 8th.—Repeat treatment.

Patient states when dyspnoea becomes more intense, as it sometimes does, in a paroxysmal manner, he increases the usual dose by several drops.

November 20th.—Repeat recipe.

December 1st.—Increase dose of convallaria to gtt. x. every three hours.

When patient is at home and in repose his breathing is much freer than formerly. While taking moderate exercise it is still very short and shallow, but if he rests for a short time afterward, his respiration again becomes relatively quiet, and is decidedly improved over what it was under like circumstances, before he began to take convallaria.

December 22d.—Patient rests quietly at night. He can sleep now lying down, but is as yet unable to work on account of debility. His appetite is poor.

During the past seventeen years he has taken a great many drugs, prescribed by various physicians, but affirms positively that he never got much relief from any medicine until the present time. Since convallaria was first taken his breathing has continued steadily to improve. The quantity of urine passed has always been abundant, and has not appreciably increased under the new treatment. Repeat medicine.

December 29th.—Feels about the same. Amount of urine passed in twenty-four hours measures one quart. Estimation was made on two occasions. Recipe as above.

Formerly, when able to work, the man had been employed in a sugar factory, and afterward in a tobacco factory.

DR. WM. M. POLK reported a case of

VAGUS NEUROSIS—EXTREMELY RAPID ACTION OF THE HEART RELIEVED BY CONVALLARIA MAIALIS.

The patient was a young man, aged twenty. Upon examining the heart to find some cause for the trouble, nothing whatever could be discovered. His other organs were normal, and their functions naturally performed. The family history was good, except that the mother had asthma, which was probably reflex from the stomach. The patient himself was a ruddy, stout boy.

He went about a year with no trouble; then, in consequence of dancing one evening, another attack was brought on which was worse than the former. He recovered from it, the heart continuing in rapid action for several hours.

He then went for a period of about two and one-half years with no trouble, and was in excellent health.

Last summer, during one of the heated terms, he was exposed a little more than usual. In consequence an

attack of rapid heart-action came on. It lasted for three days. During the first twenty hours the heart beat at the rate of 240 a minute for most of the time. He was seen during this attack by Dr. Peabody.

He got over this and was in good health until about a month ago.

On Friday evening he had a headache when he came up from his work down down. He was subject to these, however. He took some cathartic pills. Next morning he eat a light breakfast and went down to his work. In the middle of the day he walked some distance to Delmonico's and eat his lunch. He came up at six o'clock, making no extra exertion. He was then seized with one of his attacks. His heart went at the rate of 240 beats per minute. When seen half an hour later his extremities were cold; moist râles were present in the lungs, and he had the appearance of a person with acute general pulmonary congestion. He had already taken ten drops of digitalis.

I gave him ten minims of fluid extract of convallaria maialis hypodermically, and one-half hour later repeated the dose. Five or ten minutes after this the pulse dropped to 120. It did not come down gradually, but at once. The bad symptoms all disappeared in two hours. This was about half-past eight in the evening. At 4 P.M. in the morning the symptoms began to return. The dose of convallaria was repeated, and directions were left to have the drug taken every two hours in fifteen-drop doses until seen again. This dose was kept up until 5.30 P.M. It was then decreased to ten drops every three hours. During the ensuing night he had no return of the cardiac difficulty. Next morning the heart beat at the rate of about 90 per minute. The interval of dosage was increased to four hours. Next day it was discontinued, and the patient has since then been very well.

The man's habits were very good. He does not indulge in tea, coffee, tobacco, or alcohol.

The patient had been examined by Drs. Austin Flint, Metcalfe, and Leaming, and nothing wrong was found in the action of the heart in the intervals. Dr. Flint had seen a few such cases, and one of these had proved fatal.

During the attack in question there seemed to be a suspension of urine. For twenty-four hours no urine was passed, and, so far as could be told by percussion, there was little in the bladder.

Dr. A. A. SMITH said that he had been very much interested in the action of convallaria. He had used it in larger doses than had been suggested, beginning with fifteen minims and increasing up to thirty, and getting some effects if possible.

He had never used it in any case like that of Dr. Polk's.

In the case of a physician who used tobacco to excess, and who had occasionally a pulse of 190, it had occurred to Dr. Smith, while Dr. Polk had been relating the history of his case, it might be of service.

Dr. Smith was inclined to think that it produced its effect on the heart by acting on the nervous system. In that case it might have a wider use than had heretofore been supposed possible. It seemed to act upon the pneumogastric nerve. It was also, possibly, a respiratory stimulant. He had used it in two cases of sympathetic palpitation, both cases of gastric or intestinal disturbance. In one there was marked benefit; in the other, very little or no result.

In one patient, upon whom he tried it with success, there were no signs of heart disease, but

GREAT IRREGULARITY OF HEART-ACTION

as well as abnormal rapidity. The patient could feel his heart beating irregularly, and had a sense of suffocation. The convallaria was given in doses of fifteen drops every three hours, and then thirty drops every six hours, because it was thought that it was not rapidly eliminated.

Dr. Polk asked if he thought that convallaria was contra-indicated in fatty heart, as digitalis is thought to be.

Dr. SMITH did not think it contra-indicated in that condition.

Dr. GIBNEY presented a patient upon whom he had performed

ADAMS' OPERATION FOR DUPUYTREN'S FINGER CONTRACTION

six days before, with an excellent result. The deformity, as described by Dr. Gibney, and as shown by photographs, had been as follows:

Contraction of the middle finger, right hand, at the metacarpo-phalangeal articulation to an angle of 135° , and of the ring finger, same hand, to an angle of 160° ; a hard ridge of indurated palmar aponeurosis extending from the proximal end of the first phalanx to the middle of the palm, covered by the thickened skin, thrown into small rugæ; a smaller ridge for the aponeurosis connecting the ring finger with the palm. This disease had begun eight years ago; the patient, a porter in a liquor store, first observing a small nodule in the line of the transverse palmar fissure; a few years later a second one appeared, and during the past three years the deformity of the finger had been progressing. He was fifty-five years of age, a large, well-built man, and referred to Dr. Gibney by Dr. Charles W. Packard. He called attention himself, on presenting for treatment, to the extreme degree of nervousness into which he had fallen within the past year or two; had pains up the arm and in the back, and was easily frightened. This was very similar to the condition of a patient operated on by Dr. Abbe, recently reported to the Clinical Society, and also to one reported by him in the second number of *Fox's Illustrated Quarterly*. Whether the nervous symptoms in this case were reflex, or due to a central nerve-lesion, as suggested by Dr. Abbe in his own two cases, was an open question.

There was no rheumatism or gout in the man's history, and no cause could be found other than the traumatism continuously acting.

The details of the operation were described, viz.: Five small punctures with the Adams' fascia knife, and division of the bow-like chords of the fascia from without inwards, the assistant making traction on the finger meanwhile. The blade being so small, was easily introduced between the skin and bands, and the cutting was discontinued as soon as the yielding came on. Posterior splints were applied, and the deformity immediately overcome. The adhesive straps were removed four days later, and a simple steel splint, well padded, applied along palm and palmar aspect of finger. There was no inflammatory reaction whatever, and the nodular bodies disappeared immediately after the sections. Interesting, too, to relate, all his nervous symptoms had disappeared.

In the left hand the same disease existed, involving the fascia in connection with the ring finger. There was very little deformity as yet, but another operation was soon to be performed.

In the discussion on Dr. Gibney's case,

Dr. HUNTER asked if the present result was not much more favorable than is usually the case. He had had to do with several such cases, and treatment had been much more prolonged and unsatisfactory.

Dr. GIBNEY thought the result was not much more favorable than those usually reported.

In response to an inquiry, he said that he considered the nervous disturbances reflex.

The Society then adjourned.

TETANUS IN TYPHOID FEVER.—Dr. Morris Fussell, writing in *The Philadelphia Medical Times*, refers to Dr. Simoneau's case of tetanus in typhoid fever reported in *THE RECORD*. Dr. Fussell reports two cases of a similar nature. One was that of a young woman in the third week of typhoid fever, and convalescing. The patient died. In the second case, that of a farmer, aged twenty-two, recovery took place.

NATIONAL ASSOCIATION FOR THE PROTECTION OF THE INSANE AND PREVENTION OF INSANITY.

Third Annual Meeting, held at Philadelphia, Pa., January 25 and 26, 1883.

JOSEPH PARRISH, M.D., BURLINGTON, N. J., IN THE CHAIR.

[Special report for THE MEDICAL RECORD.]

THE Third Annual Meeting of this Association was more largely attended than any preceding. The papers read in full and in part were numerous and covered a wide range of topics. There were present many prominent Philadelphians, and representatives from New York and Boston. A number of asylum superintendents were also in attendance.

At the afternoon session an

ADDRESS OF WELCOME

was delivered by DR. SAMUEL D. GROSS. He said:

"The object for which we are assembled here to-day involves some of the highest principles of philanthropy, and is, therefore, well calculated to arouse and enlist the sympathies of every intelligent human being. The interest which this meeting has evoked throughout the country can only be appreciated when it is remembered that the call for it was signed by the Governor of the State, and by nearly one hundred and fifty of its most prominent and distinguished citizens, embracing two venerable bishops, learned divines, judges of our Supreme and local Courts, eminent lawyers, physicians, and laymen, all anxious to lend their influence in order to insure its success."

Letters were read from President Arthur, Governor Pattison, of Pennsylvania, ex-Governors Claflin and Rice, and Senator Hoar, of Massachusetts, and others, expressive of sympathy with the object of the meeting.

The first of the regular papers was read by PROFESSOR TRAILL GREEN, of Easton, Pa., and was entitled

THE FUNCTIONS OF A MEDICAL STAFF OF AN INSANE HOSPITAL.

He referred to the need of more skilled medical attendants in insane hospitals.

In the discussion, DR. M. PUTNAM-JACOBI, of New York, said that on one occasion the Superintendent and assistants of the Insane Asylum at Poughkeepsie, N. Y., were all away, and the whole institution was left in charge, temporarily, of an ex-assistant.

DR. SAMUEL D. GROSS offered the following resolution:

Whereas, Numerous facts have recently been brought to light tending to show that insanity in women, in many of its worst and most embarrassing forms, is caused by several diseases often of a curable nature; therefore,

Resolved, That it is the deliberate opinion of this Association that there should be upon the professional staff of every insane asylum, a thoroughly trained gynecologist, one competent to make all necessary examinations of, and to perform all necessary operations upon, women laboring under sexual maladies.

After some opposition, the resolution was amended by inserting "female practitioners preferred," before the word gynecologist.

DR. JOSEPH PARRISH read a short paper entitled

HOW TO PROTECT THE INSANE.

Some of his final conclusions were as follows:

First.—We want in every State of this Union an intelligent and faithful lunacy commission, that shall have power, under the seal of the Commonwealth, to open every door behind which a lunatic sits, examine every case, hear every complaint, and act in harmony with medical superintendents and officers of such asylums, so far as it may be possible, to secure the largest freedom

compatible with safety, and the highest intelligence in the management of the insane.

Second.—We want intermediate homes, where nervous and disordered persons, who are drifting toward insanity, may place themselves, and thus many be saved the alternative of a life in an asylum, and where convalescents who are inmates of asylums may go before resuming the duties of life and home, thus gradually entering again upon their normal life, without the shock that so frequently is a factor of relapse.

Third.—We want the people to comprehend the fact that, if they would escape insanity for themselves, they should be familiar with its causes and the manner of its approach, and, therefore need a popular journal devoted to the subject of lunacy reform and the discussion of preventive measures.

DR. CHARLES K. MILLS, of Philadelphia, read a very interesting and important paper entitled:

THE DUTY OF MEDICAL COLLEGES AND THE GENERAL PRACTITIONERS TOWARD MENTAL AND NERVOUS DISEASES.

He stated that psychological medicine stood to-day in this country where many now prominent specialties stood ten or fifteen years ago. He referred to the need of a more general knowledge and study of it. The lack of clinical lectures on mental diseases in our different colleges was especially deplored. With the exception of the University of Pennsylvania, there was no medical college in the United States where systematic clinical instruction in insanity was carried on to any extent.

At the close of the paper a resolution was adopted, requesting medical colleges to attempt the instruction of medical students in psychiatry as much as possible.

Resolutions were adopted expressing regret and sorrow at the

DEATH OF DR. GEORGE M. BEARD,

who had been one of the founders and officers of the Association, and whose talents and scientific attainments had done much toward securing its success.

At the evening session a paper was read by REV. HERBER NEWTON, of New York, entitled:

THE OBLIGATIONS OF THE SANE TOWARD THE INSANE.

It was an eloquent but somewhat sentimental plea for greater care and watchfulness toward the insane. He also urged the special training of nurses destined to have charge of insane cases.

DR. C. K. MILLS criticised the paper severely, saying that it gave an entirely wrong impression of the present condition of the insane, at least in Pennsylvania. In that State there was no danger of the wrongful incarceration of insane persons, nor were the insane brutally treated.

He was followed in the same strain by MR. FRANK WELLS, formerly of the State Board of Charities.

DR. H. MARION SIMS, of New York, read a paper entitled:

PREVENTION OF INSANITY IN CERTAIN CASES OF NERVOUS AND HYSTERICAL WOMEN.

He thought that a careful diagnosis and treatment of any diseases of sexual organs in these cases would often prevent insanity. He also asserted that there was entirely insufficient arrangements for the gynecological treatment in most insane asylums.

MR. CLARK BELL, of New York, read a paper containing much valuable matter, entitled:

THE LEGAL RIGHTS OF THE INSANE, AND THEIR ENFORCEMENT.

MR. BELL went over the whole range of English law upon the subject, and stated the ameliorative results obtained by the Parliamentary commission to inquire into the condition of the insane. He urged that there was room for improvement in the laws of his own State, and

that a general law should be passed giving Commissioners of Lunacy the right to visit and examine patients quarterly, or at least twice a year; to effect the discharge of any one who may be improperly detained; to punish for cruel treatment of patients; to extirpate mechanical restraints and seclusion, and, most important of all, to provide for the supervision of superintendents.

By unanimous vote

STANDING COMMITTEES.

were appointed on the following subjects:

To prepare a proper system of laws for the commitment and general supervision of the insane.

To collate statistics regarding insanity in the United States.

To urge a more general teaching of psychiatry in medical colleges.

Communications were received during the session from P. Piper, Prussia; Drs. Richardson, H. B. Lomas, Halthouse, D. H. Tuke, Peddie, Cloaston, J. Critchlow, Bowie, and Maudsley, of Great Britain, and Dr. Maynon, of Paris.

ELECTION OF OFFICERS.

The following officers were elected:

President, Dr. Joseph Parrish, of Burlington, N. J.

Vice-Presidents, J. S. Jewell, M.D., Chicago; C. C. Yeaman, M.D., Detroit; E. C. Seguin, M.D., New York; Mary Putnam-Jacobi, M.D., New York; C. L. Dana, M.D., New York; J. C. Shaw, M.D., Brooklyn; Hon. M. D. Follitt, Marietta, O.; Hiram Corson, M.D., Conshohocken, Pa.; Hon. R. A. Lamberton, Bethlehem, Pa.; Dr. J. P. Barcroft, Concord, N. H.; J. C. Hall, M.D., Monroe, Wis.; Hon. Joseph Perkins, Cleveland, O.; Dr. W. J. Morton, New York; Dr. Walter Channing, Boston; Garrett S. Cannon, New Jersey.

Secretary and Treasurer, Miss A. A. Chevallier, Boston.

Executive Committee, Dr. Parrish, Dr. W. B. Atkinson, Clark Bell, Esq., New York, and Dr. C. K. Mills, Philadelphia.

DR. WM. HUNT, of Philadelphia, showed to the Association a number of beautiful macroscopic sections of the brain, prepared by Dr. H. D. Schmidt, of New Orleans.

Owing to the large number of papers remaining unread, it was voted to have an extra session Friday, at 3 P.M.

SECOND DAY—FRIDAY, JANUARY 26TH.

An adjourned session was held on Friday afternoon, in order to allow the reading of papers.

DR. T. D. CROTHERS, of Hartford, Conn., read an able and original paper entitled

THE PREVENTION OF INSANITY BY THE RATIONAL TREATMENT OF INEBRIETY.

The speaker estimated that from twenty to fifty per cent. of insanity was caused by inebriety. Inebriety was a physical disease, but one that should be placed near the border-land between sanity and insanity. There were about three hundred thousand inebriates in the United States, with a yearly mortality of fifty thousand.

From inebriety come from sixty to eighty per cent. of all paupers, and from seventy to ninety per cent. of criminals.

Dr. Crothers argued that the inebriate should be recognized legally as diseased, and should be cared for by the State. Workhouse hospitals might be built from the tax on liquor traffic.

The rational treatment of inebriates is to isolate them in hospitals.

DR. CARL SEILER, of Philadelphia, read a paper on "The Connection Between Alcoholism and Insanity, or, the Relation of Inebriety as a Cause of Insanity," prepared by Dr. A. Baer, of Berlin. A paper on "Intem-

perance and Insanity," prepared by Dr. Norman Kerr, of London, was read by Mr. E. P. Allison, of Philadelphia. Dr. Charles H. Thomas read a paper prepared by Dr. J. Milner Fothergill, of London, on "Do Perversions of Assimilation Play any Part in the Introduction of Insanity?" A paper on the "Systematic Education of the Insane as a Means of Cure," prepared by Dr. James Lalor, Superintendent of the District Asylum, Dublin, was read by Dr. Ulrich, of Chester, Pa. A paper on "Some of the Conditions of Life which Influence the Production of Insanity," written by Dr. Charles Mercier, London, Assistant Superintendent of the Lunatic Asylum of London, was read by the Hon. Richard Vaux, of Philadelphia. The following, offered by Judge Peirce, of Philadelphia, was adopted:

Resolved, That the Association recommends to the careful consideration of physicians and superintendents connected with the institutions for the treatment of mental diseases, the value of regular and pleasant employment of their patients as a remedial agency in the treatment of mental disorders.

The following was also adopted:

Resolved, That the Association recommend to the Legislatures of the several States the adoption of a similar law as one passed in this State imposing penalties for issuing false certificates of insanity.

A Committee to consult about changing the name of the Association was appointed, to report March 1, 1883.

The Society then adjourned.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Special Meeting, January 29, 1883.

DAVID WEBSTER, M.D., PRESIDENT, IN THE CHAIR.

THE NEW YORK CODE OF ETHICS—ITS ENDORSEMENT BY THE SOCIETY.

THE meeting was called to order by the President, Dr. Webster, after which the Secretary, Dr. W. M. Carpenter, read the special call for the meeting signed by Drs. N. Bozeman, L. A. Sayre, T. G. Thomas, F. N. Otis, W. M. Polk, and others.

DR. D. B. ST. JOHN ROOSA offered the following:

Resolved, That the Medical Society of the County of New York approves of the amendment of the by-laws of the Medical Society of the State of New York, adopted at the annual meeting of February, 1882, and that we endorse the system of medical ethics therein substituted for the former one, especially because it leaves the matter of consultations to the discretion, the honesty, and the humanity of the individual practitioner; and although we decline to instruct our delegates to the State Society, we respectfully recommend to our representatives that they labor for the simplification of the system of medical ethics until it shall not contain specific rules for the regulation of professional etiquette, but only authorize procedure against conduct plainly unworthy a physician and a gentleman.

Dr. H. G. Piffard offered the following as a substitute:

Resolved, That the Society reposes confidence in the intelligence and integrity of the delegates recently elected by it, and that it trusts them to act in such a manner as shall best conduce to the interests of the medical profession of this city, State, and county.

After discussion, participated in by Drs. Garrish, Jacobi, A. H. Smith, and others, Dr. Roosa struck out the last clause of his resolution, when Dr. Piffard withdrew his substitute.

Dr. Dwyer next offered the following substitute to the original resolution:

Resolved, That the code of ethics recently adopted by the New York State Medical Society should be rescinded.

This was in turn discussed by Drs. Austin Flint, C. R.

Agnew, Fordyce Barker, O. D. Pomeroy, F. A. Burrall, S. O. Vanderpoel and others. The previous question was then ordered on the substitute, viz.: that the code of ethics recently adopted by the New York State Medical Society be rescinded, and the ayes and nays were demanded. The long roll was then called by the Secretary, with the following results: Ayes, 60; Nays, 147.

A motion to adjourn was put and lost. Then a standing vote was had on Dr. Roosa's motion endorsing the new code, with the result of 135 affirmative to 43 negative, and the meeting adjourned.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE TRAGEDY AT HOUNSLOW—THE PERILS OF THE DOCTOR FROM BLACKMAIL—THE COMMUNICABILITY OF PHTHISIS—HIGH RATE OF MORTALITY ON OCEAN STEAMERS—TYPHOID FEVER IN LONDON—SPONGE-GRAFTING—REOPENING OF MUSEUM OF COLLEGE OF SURGEONS.

LONDON, January 13, 1883.

YOUR readers have, no doubt, heard that a medical man at Hounslow has committed suicide under tragic circumstances. It can scarcely be possible, though, for them to realize the excitement the sad event has caused here, not only locally, but throughout the community. The facts are briefly these: Dr. W. W. Edwardes, a young medical man of thirty-two, went to Hounslow about fourteen months ago as partner in the practice of Dr. Whitmarsh. The latter had been twenty years in Hounslow, and represented that he had a general practice of about two thousand pounds a year. Dr. Edwardes paid eighteen hundred pounds for a half share. He soon became dissatisfied, and he and his partner were evidently lately on bad terms. Mrs. Edwardes asserts that the amount of actual cash received by her husband during the first twelve months was only £180, of which sum £160 were absorbed in keeping his carriage. The day before Christmas day Dr. Edwardes received a letter from a laborer's wife, whom he had been attending for some nervous and uterine trouble, charging him with having behaved improperly to her on the previous day and threatening proceedings. The deceased at once communicated the fact to his partner, his wife, and his father-in-law, and asserted the falsity of the charge. The woman, in fact, afterward retracted it, and, together with her husband, signed a written retraction and apology, which was also signed by Dr. Whitmarsh as a witness. She seems to have subsequently renewed the charge, saying that although she had consented to withdraw it, it was virtually true. Dr. Edwardes then determined to prosecute her for libel.

In the meantime, however, Dr. Whitmarsh endeavored to induce Dr. Edwardes to withdraw from the practice and dissolve the partnership for the small sum of five hundred pounds. It appears that on the night of the death of Dr. Edwardes the solicitor of the woman in question met Dr. Edwardes at Dr. Whitmarsh's house and threatened the former to obtain a warrant for his immediate apprehension. Dr. Whitmarsh, it appears, took occasion to renew his efforts to dissolve the partnership on very unfavorable terms to Dr. Edwardes. The latter appears to have gone home in great distress and to have committed suicide with prussic acid almost immediately. The whole of the facts are not yet before the public, as the inquest is still proceeding.

The public feeling at Hounslow has been so strong that the surviving partner has been compelled to leave the town for a time, and his house has been attacked by a mob of several thousand persons. The woman who made the

charge has not yet been examined before the coroner, but from what has been already elicited respecting her character, her evidence does not seem likely to be worthy of much credence.

Dr. Edwardes was an industrious student, very popular at his hospital when resident obstetric officer, and appears to have gained the esteem of his fellow townsmen, although he had been but a short time at Hounslow. He was, however, a singularly nervous, sensitive, reserved, and in some respects, eccentric man. I can quite corroborate the evidence given on this head from my personal knowledge of him. When a student at St. Mary's Hospital, he refused to compete on one occasion in a class examination for which he had been working hard many months, simply because a fellow-student would not exchange numbers with him and let him go in first for the *viva voce*.

The Collective Investigation Committee of the British Medical Association have issued a circular on the "Communicability of Phthisis." The general consensus of opinion amongst the profession at present would seem to be that it *may* be communicated under some circumstances, but that such communication does not often occur. The *British Medical Journal*, in a recent article, enumerates some instances apparently showing the transmissibility of phthisis from patients to persons brought into close relation with them. The writer does not mention, however, one possible explanation of such cases, viz., that, as Dr. Henry MacCormac, of Belfast, has suggested, the disease may be induced in healthy persons by breathing and re-breathing their own pulmonary exhalations when confined either alone or with invalids in a badly ventilated chamber.

Attention has lately been called to the high rate of mortality among passengers on steamers crossing the Atlantic. It has been stated that the sanitary arrangements on these vessels may be partly to blame. Another explanation is the unsatisfactory position of ship surgeons. They are badly paid, worse lodged, and their recommendations on sanitary matters often treated with contempt. In any case, they have no authority to enforce their recommendations.

Typhoid fever is still prevalent both in London and in Paris. In spite of the progress made in sanitary matters and the improved systems of drainage, I cannot help thinking from my own personal experience of both cities that much still remains to be done and that the present state of affairs is accountable for much of the typhoid now prevalent. In London, if not in Paris, the main drainage system is now complete and mostly in good order, but the drainage of individual houses is often defective. I have been in many West-end houses in which the water-closets were placed in the centre of the house and ventilated only on to the staircase. I noticed this arrangement in the town house of the late Earl of Beaconsfield in which he died.

Several cases of successful sponge-grafting have lately been reported.

Professor Owen's friends are very anxious about his health.

The President of the College of Surgeons, Mr. Spencer Wells, held a reception at the College of Surgeons, this afternoon, on the occasion of the re-opening of the Museum after extensive repairs. Most of the leading men were present. The improvements in the Museum met with general approval.

BUBO MAY BE A BIRD.—The *Boston Medical and Surgical Journal*, November 2, 1882, contains the following warning: "Lest any of our readers may misunderstand a statement in the daily press that a specimen of *Bubo Virginiana* was lately seen in Pemberton Square, we take occasion to explain that this is merely the expression of the scientific reporter for the great horned owl which lately appeared in that locality."

THE CARE OF THE CHRONIC INSANE.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I have always been opposed to the distinction between hospitals for the acute and chronic insane, and am not in any way responsible for any regulation or usage by which the Hudson River State Hospital has obtained the distinction of being for the acute insane alone. The allusions made by Dr. Chapin, in his letter to your journal of January 20th, to myself, have therefore no pertinency whatever to the question as to the "scientific," "humane," and "economic" care of the insane in our State.

Every person of ordinary intelligence in our State knows that the chronic insane are better treated in the asylums for the chronic insane than they are, or ever can be, in the county poor-houses. Every one at all familiar with the Willard Asylum, which is under the care of Dr. J. B. Chapin, your correspondent, knows how admirable it is in many of its provisions. What I object to is the absence in our State of any broad plan for the "scientific," "humane," and "economic" care of the insane as a great class, including acute and chronic cases. At present there is no such plan. County officials naturally send county insane where they can be treated the cheapest. At this time they are sending all portable cases across the State to Willard and Binghamton, because in those places the rate of board per week is lower than it is possible to make it at the State Hospital at Poughkeepsie, or in any other State or private asylum, on the basis of present number of inmates. When the State Hospital was first opened at Poughkeepsie it cost nearly thirteen dollars a week to keep a patient, because the population of the hospital was small and every item of expense in attendance and maintenance was divided among a few only. An establishment had to be maintained on the basis of a few patients which would have been adequate for three times their number. As the population in the hospital increased, the expense per head went down to less than half the original cost; but it has been impossible to make the cost, on the basis of two hundred and fifty or three hundred patients, the present population, as low as Dr. Chapin can make it on a basis of fifteen hundred or two thousand patients. Through the favor of the State Board of Charities, and through opinions favorable to the western part of the State, and legislation procured to maintain asylums for the chronic insane, we now see the remarkable process going on of drafting the insane from the eastern counties of our State to fill and compel the enlargement of Willard and Binghamton. Of course this depletes the State Hospital at Poughkeepsie, advances the cost of board in that institution, and makes it therefore more and more unpopular with county supervisors and superintendents of the poor. New York and Kings County, and some others, are out of the calculation, because in those counties they undertake to provide for their insane, and having large numbers to provide for, keep down the per capita cost to a very low figure—much lower, let us say, than the immediate interests of the insane justify, or the remote interests even of the taxpayer make desirable.

Now let me say in a word what I think should be done. Stop sending the chronic insane from Hudson River or eastern counties to Willard or Binghamton after those institutions are full, and use the three hundred acres owned by the State at Poughkeepsie, in connection with the State Hospital, for such cheap model lodging-houses and workshops as would afford sanatoria and schools not only for such cases as become chronic in the halls for the treatment of the acute there, but to relieve the overcrowding at the hospitals in New York and Kings Counties.

The cost of the care of the acute insane will always be four or five-fold greater than that of the chronic insane. Sixty or seventy per cent. at least of the chronic insane are available for such industries as would provide, meas-

urably, not only for their own support, but to lessen the cost to the State of the care of the acute insane. A hospital for the care of the acute insane should be allowed to retain within its precincts a sufficient population to secure a "scientific," "humane," and "economic" care of all classes of its beneficiaries. I am in full accord with Dr. Chapin regarding the cruelty of taking insane persons to common county houses. It should be forbidden by law. I urge, and I trust with his approval, that every existing State hospital be not only allowed but compelled to provide for its chronic insane, so far as possible, within its own precincts.

I do not propose, by carrying one thousand or fifteen hundred patients from New York and Kings County to Poughkeepsie, to make that institution another chronic asylum, as he alleges I do, but only to make it an economic success, and to relieve the crowded institutions of New York and Kings Counties, and prevent the present expensive and objectionable method of transporting chronic patients from eastern counties to keep Willard overfull, and apparently justify the objectionable proposition to enlarge the Chronic Asylum at Binghamton.

If New York County and Kings choose to get farms of their own on which to colonize their chronic insane, I shall not object; but it does seem to me that the State property at Poughkeepsie should be turned to better account than it now is. That institution must be enlarged for the accommodation of the chronic insane in its vicinity, or else shut up.

Yours faithfully,

C. R. AGNEW.

"MEDICAL LATIN."

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: This being my earliest opportunity, may I claim the privilege of a few words as to Dr. Rice's "rejoinder" to the article of mine entitled "Medical Latin," which appeared in THE MEDICAL RECORD of November 18th?

The Doctor alleges that "the paper contains some incorrect and misleading statements, which, if left uncontradicted, might" have a certain mischievous effect.

Briefly, the statements are that such nouns as *carbonas*, etc., are rightly classed as feminine and of the third declension, and that *rhus*, the fruit, is neuter.

Dr. Rice holds, on the contrary, that such words as *carbonas* are not substantives, but adjectives in concord with subintelligible substantives of the masculine gender, and that *rhus* is feminine, whether tree or fruit.

I do not propose to contradict Dr. Rice's assumptions; but honestly believing them to be erroneous, shall endeavor to show why I so believe.

The Doctor, in his "rejoinder," presents no arguments, but dwells on the fact that, in certain discussions regarding pharmacopœial nomenclature, "it has been shown that there is no analogy whatever in Latin for the feminine gender in the case of these nouns, it being altogether wrong to bring them into one category with the large class of Latin feminines ending in *-tas* (as *æstas*, *pietas*, *brevitas*, etc.)." He then refers us to certain arguments in *New Remedies*, 1882, p. 58, and adds: "It may be considered as finally settled that these terms should only be used as masculines." *Longè aliter censeo.*

Having read the article. I think I am prepared to prove that it refutes itself. Let us see (second paragraph):

"When the chemical terms sulphate, nitrate, carbonate, sulphite, etc., were first introduced and translated into Latin for pharmaceutical use, about the beginning of the present century, the different translators used them in various genders, according to their judgment," etc.

Which being so, the question arises, What, grammatically, are the terms sulphate, carbonate, etc.? Substantives or adjectives? That they are not adjectives is proved by the fact that they will not unite in grammati-

cal concord with any substantive, except in apposition. What say the dictionaries? The dictionaries decide unanimously that they are substantives, each representing abstractly a chemical combination.

How, then, should they have ceased to be substantives by being *translated* word for word into Latin? The writer admits, in effect, that by changing *-ate* into *-as* and *-ite* into *-is*, they are "translated into Latin," but insists, this having been done, that they are no longer substantives, but adjectives agreeing with *sal* understood.

But, if a single noun cannot be translated from one language into another by a single word, we are always obliged to resort to periphrasis, and every supplementary word necessary to the sense must be expressed, or we have imperfect sense or stark staring nonsense. Adjectives like *Capenas* will not supply the place of nouns like carbonate; adjectives like *Capenas*, found without a substantive expressed, invariably refer to persons, not to things.

Having assumed that such nouns as carbonas are adjectives, the writer is at pains to prove it by trying to show that they cannot be substantives. Hence he would have it that they do not belong to the large number of feminine nouns in *-tas*, making the genitive in *-ātis*, because their nominatives do not end in *-tas*; they cannot be classed with Greek feminines in *-as*, because their genitives do not end in *-adis* or *-antis*; nor with Greek neuters in *-as*, *-ātis*,¹ the *a* in the genitive of *carbonas*, etc., being long. He admits, however, that the termination *as* (*-ātis*), "which is the same as that in our modern terms *sulphas*, etc., does occur in Latin," and enumerates among instances "some technical and fanciful terms, like *anas*, *anātis*, old womanhood," but adds: "This noun is feminine, but really belongs to § 5 above" (nouns in *-tas*), "as it is contracted from *anitas* (*anītātis*)."

The termination *-tas* in the nominative is of no moment, as I shall presently show. That which in these pharmaceutical nouns demands the classification, which is claimed for them in "Medical Latin," is the genitive in *-ātis*. The genitive being in *-ātis* (not *-ātis*), they fall within the category of nouns so forming the genitive, no matter what the nominative may be. Did they make the genitive in *-adis*, *-antis*, or *-ātis*, we would as promptly refer them to the class thereby plainly indicated.

On the writer's own argument we might insist that *acetas* is a noun in *-tas* as much as *astas*. But wrongly, for it cannot be said that the *t* in *acetas* belongs to the termination, for it is part of the root in *acetum*; and in this particular the right of *acetas* and its analogues to this classification is approved by the admission of *astas*, which is in precisely the same predicament, the *t* (which occurs also in its primitive, *æstuo*) being part of the root, not of the suffix.

But were we disposed to maintain the claim of all our pharmaceutical nouns in *-as* to this classification, we would be sustained by the writer's own admission that the feminine *anas*, *anātis*, is contracted from *anitas*, *anītātis*.

The "translators," desirous of names as homophonous as possible to the original substantives, had warrant, most assuredly, in the examples of *anas* for *anitas*, and *satias* for *satietas*, in writing *acetas* instead of *acetitas*, etc.

As regards *sulphis*, etc., the writer insists that there is only one true Latin noun in *-is*, *-itis*, namely *lis*,² the lawsuit, which is feminine, but that there are a number of geographical and patronymic adjectives in *-is*, *-itis*, to which *sulphis*, etc., belong.

But *sulphis*, etc., being substantives translated, like *sulphas*, etc., are substantives themselves, and can follow only the analogy of *lis* in making the genitive in *-itis* and taking the feminine gender.

With regard to the Latin *rhus*, authorities differ.

¹ Among examples in *-as*, *ātis*, he mentions as a true Latin word *anas*, a duck. No philologist would so characterize it. It is a metaphor of *ῥῆσα*; theme, *ῥω*, whence Latin *no*, to swim. In the same way the German *ross* becomes the English *horse*.

² *Lis*, *ditis*, the god, is a very good Latin noun substantive; *dis*, *ditis*, rich, a good noun adjective of all genders. Neither of them is patronymic or geographical, or signifies descent.

Ainsworth gives *rhus*, -i. m. and f., the tree; *rhus*, -i. n., the seed or berry, quoting for the latter Pliny and Celsus, without reference to edition. Andrews gives *rhus*, *rhois*, and the accusatives, *rhūn* and *rhūm*. According to the reading preferred by Dr. Rice, Celsus made the tree masculine; and, inasmuch as the Latin of Celsus is unimpeachable, it is unfortunate for his argument in favor of *rhus glabra*. But the Doctor admits that, "in later writers, *rhus* occurs as neuter." Yes; and why? Because it is agreeable to the idiom of the language. Though Dr. Rice calls the rule for neuter fruit names "an alleged rule," it is a rule which is acknowledged by all scholars.

The Doctor says that *rhus* is not of the second declension; that "in Latin, it belongs to the third declension, and has the genitive¹ usually *rhois*."

He errs. *Rhūs* (Greek *ῥῶς*), in Latin, forms its genitive singular usually according to the third declension, *rhois*; and its accusative, according to the Greek second declension, *rhūn*; and, according to the regular second declension, *rhūm*.

Referring to the genitive, he says, in a note: "In Greek, the corresponding noun may take the terminations" (termination?) "of either the second or third declension—*ῥῶν* or *ῥῶς*."

It has a much larger variety of inflection. It may make the nominative singular according to the second declension, *ῥῶς*, or according to second or third, in the contracted form, *ῥῶς*; the genitive, according to the second *ῥῶν* or *ῥῶν*, and according to the third, *ῥῶς* or *ῥῶς*, the accusative singular according to the second, *ῥῶν* or *ῥῶν* (*rhūn*), and in the third declension, *ῥῶς*.

The Doctor declares with emphasis: "The form, *rhūm*, is the accusative singular of the third declension!"

Such it is not; and it is still for Dr. Rice to produce the first recorded instance of an accusative of the third declension, Greek or Latin, ending in *um*.

If *rhus*, like other Latinized Greek nouns, had an accusative of the third declension, it would be *rhoa*, as in Greek.

The Greek diphthong *ōū* was pronounced like long *ū*. The Romans, in spelling Greek words with Roman letters, substituted *ū* for this diphthong. Thus we have *rhūis* for *ῥῶς*, *chirūrgus* for *χειρουργος*, *Œdipūis* for *Οἰδίπους*; *rhūn* for *ῥῶν*, contracted from *ῥῶν*, the regular Greek accusative singular of the second declension.

One objection of Dr. Rice to *rhus glabrum*, is that *rhus* here being supposed to mean the fruit, *glabrum*, which has especial reference to the tree, cannot be predicated of it. With equal reason, he might object to the English name, sweet chestnut, applied to the tree, though the adjective serves to show that the tree meant is not the one which bears the horse-chestnuts, but a different one. *Rhus glabrum* does not mean the glabrous fruit of the *rhus*, but the fruit of the glabrous *rhus*.

The Doctor refers, in a note, to one Palladius Martialis. Who was he? There was a Palladius Rutilius Taurus, usually quoted as Palladius, who wrote on rural affairs and called the divisions of his principal work after the months; one of them being *Martius*; but I nowhere find mention of Palladius Martialis.

Dr. Rice charged me with having made "some incorrect and misleading statements," which he proposed should not go "uncontradicted." He has accordingly contradicted much, without, in my opinion, disproving anything.

Very respectfully,

JOHN A. ARMSTRONG.

BROOKLYN, E. D., January 19, 1883.

LONDON SMOKE.—London has only about 24 per cent. of sunny days, while towns near by have, on an average, 12 per cent. more.

¹ *Genitīvus* is formed from *genitum*, supine of *gignere*. The Greek name is *γεννη-πῶσις*.

² *ῥῶς ἑξάνθητα καὶ κοπέντα*.—Galen.

TWO CASES OF CARDIAC ASPIRATION.

TO THE EDITOR OF THE MEDICAL RECORD.

THE interest excited by Dr. Westbrook's very suggestive article on abstraction of blood from the right heart leads me to refer to two cases which came under my notice several years ago.

A young woman, aged about twenty-five, was suffering from acute nephritis. She was admitted to Bellevue Hospital and was under the care of the House Physician, Dr. P. M. Chadwick, in the fall of 1877. One afternoon, while sitting up in bed, and being apparently in fair condition, she suddenly fell over and ceased breathing. Heart action soon ceased. All possible means of restoration were used, but without success, by Dr. Chadwick and myself. Finally, Dr. E. G. Janeway, in whose service the case was, suggested the aspiration of the right ventricle. A veterinary hypodermic needle was inserted between the fourth and fifth ribs, a little to the left of the sternum, and half an ounce of blood drawn off. No result followed.

I have only meagre notes of this case and cannot recall the results of autopsy.

The second case, which occurred in my service in April, 1878, was that of an Irishman, a hard drinker, aged thirty-eight, slightly built and anæmic, who was suffering from acute lobar pneumonia in left lower lobe.

The disease did not progress very favorably. On the eleventh day he still had consolidation; temperature, 102°; pulse, soft; general condition, weak; slight signs of œdema of lungs. Large doses of whiskey and ammonia were given, also digitalis. In the afternoon the patient was suddenly attacked with tonic and clonic convulsions. Respiration and convulsions soon ceased; the heart continued to beat, however; artificial respiration, injections of ammonia, ether, inhalations of nitrite of amyl were applied in vain.

I then, at the suggestion of Dr. Janeway, inserted the hypodermic needle into the right ventricle and drew off an ounce of fluid blood. It produced no effect.

Post-mortem showed the trace of the needle through the heart-tissue and the right ventricle was empty.

I do not consider puncture of the right ventricle a difficult or even very dangerous operation. In experimenting upon dogs and cats I have often stabbed and pricked the heart substance, with the result sometimes of stimulating, never of checking its action. I would not advise aspiration of the right auricle, however, under any circumstances. Not because it is necessarily dangerous, but physiologists are agreed that the auricle is chiefly a regulator and reservoir, not a propelling muscle. The unloading it could have little effect on the work of the heart.

Cardiac aspiration may be indicated in cases of sudden heart paralysis, when the ventricle is presumably over-distended. The needle may possibly relieve over-distention, and by its irritation set the heart to work again. It is decidedly a last resort and was not tried in the two cases reported until every other measure was exhausted. In cases of laboring heart I should vastly prefer venesection, whose potency is unquestionable.

C. L. DANA, M.D.

Army News.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from January 20, 1883, to January 27, 1883.

WATERS, WILLIAM E., Major and Surgeon. Detailed as member of Army Retiring Board, to convene at Fort Porter, Buffalo, N. Y., February 2, 1883. S. O. 21, par. 1, A. G. O., January 25, 1883.

HEIZMAN, CHAS. L., Captain and Assistant Surgeon. Will be relieved from duty in the Department of the

Columbia, and ordered to report to the Commanding General Department of the South for assignment to duty. S. O. 20, par. 10, A. G. O., January 24, 1883.

KILBOURNE, H. S., Captain and Assistant Surgeon. Leave of absence for one month, with permission to apply for an extension of two months, is granted. S. O. 218, Department of Dakota, December 21, 1882.

PRICE, CURTIS E., Captain and Assistant Surgeon. Detailed as member of Army Retiring Board, to convene at Fort Porter, Buffalo, N. Y., February 2, 1883. S. O. 21, par. 1, A. G. O., January 25, 1883.

SKINNER, JOHN O., Captain and Assistant Surgeon. Will report in person, at the expiration of his present leave of absence, to the Surgeon-General for duty in his office. S. O. 20, par. 10, A. G. O., January 24, 1883.

SPENCER, WM. G., Captain and Assistant Surgeon. The leave of absence on Surgeon's certificate of disability, granted September 20, 1882, is extended three months on Surgeon's certificate of disability. S. O. 16, par. 4, A. G. O., January 19, 1883.

TAYLOR, MARCUS E., Captain and Assistant Surgeon. Will report in person, at the expiration of his present leave of absence, to the Commanding General Department of the East, for assignment to duty. S. O. 20, par. 10, A. G. O., January 24, 1883.

WOOD, MARSHALL W., Captain and Assistant Surgeon. Will be relieved from duty in the Department of the East, at the expiration of his present leave of absence, and will report in person to the Commanding General Department of the Columbia, for assignment to duty. S. O. 20, par. 10, A. G. O., January 24, 1883.

WOOD, MARSHALL W., Captain and Assistant Surgeon. At expiration of present leave of absence, relieved from duty in the Department of the East. S. O. 15, par. 1, Department of the East, January 26, 1883.

WYETH, M. C., First Lieutenant and Assistant Surgeon. Is relieved from duty at Fort Snelling, and will proceed to Fort Stevenson, Dakota Territory, and report to the Commanding Officer of that post for duty. S. O. 15, par. 1, Department of Dakota, January 18, 1883.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Comparative statement of cases of contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending January 27, 1883:

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
January 20, 1883	0	10	62	9	55	43	2	0
January 27, 1883	0	10	59	3	80	44	0	0

NEW BOOKS.—One hundred and nineteen new books, and fifty-eight new editions, upon medical and surgical subjects were published in Great Britain in 1882.

A HOMŒOPATHIC physician in Switzerland advertises that he performs "surgical operations *milder* than any physician of the other school." At last we know what a homœopathic surgeon is.

INTERNATIONAL MEDICAL CONGRESS FOR 1884.—It is announced by the Secretary-General of the International Medical Congress that the eighth session of that body will be held in Copenhagen during the days from the 10th to the 16th of August, 1884.

THE ETIOLOGY AND TREATMENT OF CERTAIN FORMS OF NON-PUERPERAL UTERINE HEMORRHAGE.

By PAUL F. MUNDÉ, M.D.,

PROFESSOR OF GYNECOLOGY AND OBSTETRICS AT THE NEW YORK POLYCLINIC; PROFESSOR OF GYNECOLOGY AT DARTMOUTH COLLEGE; GYNECOLOGIST TO MOUNT SINAL HOSPITAL, ETC.

I DO not propose to discuss all the pathological conditions which may give rise to uterine hemorrhage in the non-puerperal state. While doubtless something new might still be said on the menorrhagia and metrorrhagia produced by carcinoma of the cervix and body of the uterus, by intra-uterine villousities, by fibroid tumors, by displacements and the therefrom resulting hyperæmia, by chronic ovarian congestion and inflammation; and while there may still be points of interest and doubt both as to the pathology and treatment of these conditions, I intend to limit my remarks to several etiological factors in the production of hemorrhage from the non-puerperal uterus, which seem to me rather less common and less recognized than those above referred to. In discussing this subject I beg to be understood as speaking of either profuse *menstrual* flow, or of a bloody discharge in the *inter-menstrual* period, when using the term "hemorrhage." The predominating variety will be specified at the proper place.

1. *Non-puerperal erosion of the cervix uteri.*—That blood may and does ooze from an abraded surface either of skin or mucous membrane, even though the abrasion be merely that of epidermis or epithelium, is an old story; and that this may take place on the cervix uteri, is also well known; but I do not think it is sufficiently recognized that, in certain instances, a more or less marked increase of the menstrual flow, or an inter-menstrual sanguineous discharge, or a constant bloody oozing, may be due to nothing but an apparently trifling superficial erosion of the vaginal portion of the cervix uteri. Such patients may have been treated by ergot, acids, and other hemostatics, by astringent injections, by rest and ice, with but temporary arrest of the oozing, until finally a specular examination is made, and the bleeding found to proceed, not from the uterine cavity, but from the eroded cervix. Only by a speculum can this diagnosis be made, for the finger can but suspect it if the surface of the cervix is felt to be particularly soft and velvety; and this suspicion may become almost a certainty if blood is found on the finger when it is withdrawn.

On exposing the cervix with a speculum, the whole or a portion of it is seen to be of a bright red color, with a rough surface, which bleeds readily on being wiped with cotton. This erosion may be situated on both the anterior and posterior lip, or on one only; in anteversions on the anterior, in retroversions on the posterior lip. The cause of this situation of the erosion depends on the cause of the lesion itself, namely, on the almost invariably present cervical catarrh. According as the profuse acrid discharge flows chiefly over the anterior or the posterior lip, is the erosion found on the respective lip.

In appearance the erosion resembles the well-known fruits, the tomato, the raspberry, and the strawberry. If the epithelium is merely abraded the surface looks raw, deep red and shiny, with dilated blood-vessels crossing

the field, not unlike the surface of a full-ripe tomato; if the papillæ also are enlarged, we see numerous bright-red elevations, like the tomato with its skin removed, or like the ridges on a raspberry; and if, in addition to these, the cervical glands are distended and filled with white or yellow opaque mucus, we have between the red papillæ yellowish white dots, similar to the seeds of a ripe strawberry. This description may seem, and, of course, is somewhat fanciful; still, it conveys fairly well the appearance of and difference between these three stages and forms of cervical erosion.

This lesion is found in virgins as well as married women, both nulliparæ and parous. I have seen young girls with intact hymen, who consulted me for profuse glairy, yellow discharge, menorrhagia, and "spotting" in the interval, the cause of which was such a cervical erosion; and married women who had had no children, or had not been pregnant for many years, in whom the cervical epithelium became abraded for some mysterious reason.

As a rule, the causes of this lesion are twofold: 1, catarrhal discharge from the cavity of the cervix, and, 2, friction of the cervix against the posterior vaginal wall. The fact should not be overlooked that in poorly nourished, debilitated women, such an abrasion of epithelium is much more liable to take place than in strong, healthy females.

The form of erosion to which I now refer is *not* that produced by and found combined with eversion of a lacerated cervix. The simple erosion is situated on the outer surface of an otherwise entirely sound cervix.

The chief symptom produced by this simple erosion is the profuse, greenish-yellow or sanious discharge, which annoys, and, in course of time, debilitates the patient. If a young girl, she is distressed by the soiled linen which the laundress naturally criticises, and by the constant moisture of the vulva; if a married woman, she fears possible injury to her husband, and consequent unjust suspicion of herself. But not this alone. In addition to the discharge, the menstrual period is more profuse or prolonged, and bloody spotting of the linen is observed in the interval. This loss of blood is usually not serious, but its recurrence and continuance not only mentally but physically depresses the patient, until she consults her family physician, who, especially if she be an unmarried girl, naturally feels averse to making an examination, and prescribes mild astringent injections, and possibly tonics, if anæmia is present. The latter medication eventually does good; the former is at the best palliative, and sooner or later the patient consults a specialist, who makes the necessary examination, and discovers in the described erosion the cause of all the trouble. A mere cleansing of the eroded surface with cotton on the forceps is followed by the oozing of blood from every enlarged and uncovered papilla, and from the external os hangs a plug of thick green mucus.

The *diagnosis* of this condition is much easier than its cure. I have found the following treatment effectual in all the cases which have remained under my care for a sufficient length of time to achieve a cure. The cervix is exposed either through a Sims or cylindrical speculum (the latter answers as well or better), carefully wiped dry with absorbent cotton, and the tenacious mucous plug is sucked out of the cervical canal by a long uterine syringe, or by dry cotton, or a small sponge on a dressing-forceps. This accomplished, a solution of nitrate of sil-

ver, ʒj. to ʒj. is applied on a cotton-wrapped stick within the cervical canal and thoroughly over the eroded spot. A thin dust of finely powdered iodoform is then blown on the cervix through an insufflator, a tampon soaked in glycerite of tannin, equal parts, placed against it, a dry pledget over this, and the speculum is withdrawn. These tampons are to be worn for thirty-six to forty-eight hours, and an injection of tepid water, with one to two drachms of sulpho-carbolated zinc or plain sulphate of zinc should be used twice a day for three days, when the patient should again present herself for local treatment. The same application will probably be repeated every three days, until the erosion shows signs of healing, when a milder solution of nitrate of silver (ʒ ss. or gr. xx. per ounce) should be used; or the absence of improvement calls for a change of treatment. In very obstinate cases, with chronic cervical catarrh, it is essential to cure the latter (the cause of the erosion) first, and this is a difficult matter. The removal of the hypertrophied endo-cervical glands and mucous membrane by the sharp curette and cauterization of the base with strong nitric acid or the actual cautery, is usually an indispensable preliminary to a successful treatment of the catarrh. Occasionally I have found it necessary to apply nitric acid, or pure chromic or pyroligneous acid to the erosion, before a change for the better allowed me to return to the milder astringents and iodoform. In every case it is well to notify the patient that the cure is certain, but that she must persevere for several months, at least, or she will not recover.

In a few intractable cases I have found the negative pole of a galvanic battery, applied by means of a round button to the erosion, the positive sponge being placed over the abdomen, to produce a marked tendency to cicatrization. In one such case, the last resort of grafting healthy mucous membrane on the erosion, as practised once by Dr. R. W. Amidon, occurred to me, but the galvanic current finally produced a cure. Had neither of these methods succeeded, an unfailing remedy would have been the paring of the erosion with scissors (as in Emmet's operation for laceration) and the union of the raw surfaces by sutures. This method was already proposed by me in my paper on the "Indications for Hysterio-Trachelorrhaphy," published in the *Journal of Obstetrics* for January, 1879. While the usual symptom of these erosions is the profuse mucous discharge, the menorrhagia and inter-menstrual oozing produced by them is by no means uncommon. That this latter symptom is not usually attributed to so simple a lesion as a superficial erosion of the cervix, is my impression, and the reason why I have thought the subject a proper one for discussion. A typical case, which occurred in my practice some time since, may serve as an illustration of my remarks, and of the failure of the ordinary measures to arrest the hemorrhage, so long as its real cause was unrecognized and untreated.

CASE I.—Mrs. —, aged forty-two, mother of one child, now in his twentieth year, had always been in fair health, although not very strong, until some two years ago, when she began to menstruate more profusely than ever before, but without pain or special inconvenience. Gradually, however, she began to experience pain in the left ovarian region, and in the fall of 1881 the menorrhagia became so profuse as to confine her to her bed for more than one month. Her physician, a gentleman very eminent in another specialty, treated her by ergot by the mouth, by rest, and on two occasions by tampons introduced through a cylindrical speculum. The hemorrhage was arrested by this latter remedy, and the lady was assured by her physician, that no doubt the next menstrual period would be normal, if she would only remain quiet until it had passed. She therefore remained in bed, but, to her disappointment, the period appeared as profusely as before, with acute pain in the left ovarian region. When it had continued a week, the lady decided to consult a specialist, and discharging her former physician, who had not visited her for several

weeks, sent for me. I found a nervous, anæmic woman, who plainly showed the effects of suffering and loss of blood. After obtaining the above history, I suspected that the menorrhagia was due to ovarian congestion, and as the lady was bleeding quite profusely, decided first to try the effects of ergot by the rectum and a blister over the left ovary, with dilute aromatic sulphuric acid, before making a vaginal examination. I accordingly ordered suppositories, each containing five grains of Squibb's aqueous extract of ergot, three times daily, and, as required, other suppositories with two grains extract hyoscyamus and one-fourth grain extract belladonna to relieve the ovarian pain (the lady asserted that she could positively not take opium). I assured her that the hemorrhage would probably cease in a day or two, and that then I would make a vaginal examination and endeavor to ascertain the cause of the bleeding. But, to my surprise, a week passed and still the oozing continued, and the patient began to be alarmed, as her menstrual period had now lasted two weeks. I accordingly determined to make an examination at once, and found the uterus anteverted, the vaginal pouch rather narrow (as though contracted by senile atrophy), and the left ovary decidedly enlarged and tender. The cervix had a peculiar soft, velvety feel, which induced me to make a specular examination, which I did through a Sims, and on wiping the cervix clean I at once discovered the source of the hemorrhage in a flat, superficial erosion of the size of a twenty-five cent piece on the anterior lip. I could positively determine that no blood issued from the os, and could see it oozing in drops from the erosion when I wiped it with cotton. I informed the lady of this fact, discontinued the ergot suppositories and the sulphuric acid, and at once brushed the cervix over with tincture of iodine (this being the only agent I had with me), and inserted a tampon with glycerite of tannin.

Two days later I painted the erosion with a solution of nitrate of silver (ʒj. to ʒj.), and reapplied the tampons, and this treatment was continued for about six weeks, fifteen applications being made in all, six at her residence, the remainder in my office. After the first two treatments the hemorrhage ceased entirely, and with it the ovarian pain; in less than two weeks the patient was able to come to my office, and in two weeks more the erosion was healed, the subsequent applications being chiefly of iodoform and tannin (equal parts), blown on the cervix in order to toughen it still more. The menstrual period, which came on about one month after I began treatment, was perfectly normal in quantity and duration, and painless, and has so continued up to the present time, and the lady has gained more in strength and flesh than during many years past.

In this case I think the erosion was due to the friction of the cervix against the contracted vaginal pouch; there certainly was no cervical catarrh or vaginal leucorrhœa.

A very similar case was reported by Dr. Pallen, at the meeting of the New York Obstetrical Society held May 3, 1881, at which I was not present, and the first notice of which I had while correcting proof of the proceedings of that meeting for the January (1882) supplement of the *Journal of Obstetrics*, at which time I was already treating the case just related. Dr. Pallen's case was that of a girl of fifteen, who had become greatly prostrated by menorrhagia. Other means having failed to check the hemorrhage, a specular examination was made, and a condition of the cervix discovered "which resembled very closely the catarrhal condition of the vaso-pharyngeal mucous membrane, and from its surface, which was denuded of epithelium, there oozed forth blood in great drops." A similar treatment to that described by me, together with tonics, etc., cured the case.

I wish it distinctly understood that the bleeding surface may be merely the most superficial erosion, and that the so-called "granular degeneration of the cervix" is by no means necessary to produce menorrhagia. That the latter more aggravated form of cervical disease produces that

result is well known. The chief point to be made from the preceding remarks is that a profuse menstrual flow may often depend on a lesion of the cervix, which is discoverable only by the speculum, and curable only by local applications; and that in severe cases it may be advisable to make such an examination, and use such treatment even during the menstrual period itself.

2. *Laceration of the cervix unhealed or temporarily healed.*—One of the most frequent sources of hemorrhage is undoubtedly a cervical laceration. Not only does the blood flow freely at irregular intervals from the eroded surface of the hyperæmic and hyperplastic everted lining membrane of the cervical canal, but also does the subinvolution and engorgement of the whole uterus maintained by the lesion entail menorrhagia. It is not of the large lacerations that I wish to speak, but of the minor degrees, in which the larger part of the everted surface has healed spontaneously, or been glazed over by astringents, frequently, however, leaving a small patch of hyperplastic papillæ or granulations just within the cervical canal. These granulations bleed readily on touch during coition, and often from friction during walking. This can be felt by the examining finger, and easily recognized through the speculum. The hemorrhage produced by these granulations is usually not sufficiently profuse to be serious; it is chiefly the annoyance of more or less constant oozing, and of frequently soiled linen, which induces such patients to consult a physician. The treatment is very simple, and consists in exposing the cervix thoroughly through any speculum of sufficient size, and with fine curved scissors snipping off these exuberant papillæ, or scraping them away with a sharp curette; their base is then seared with strong nitric acid, and the usual astringent after-treatment pursued until the surface is completely healed. So long as the cervical canal gaps, a return of these granulations is not improbable; a permanent cure therefore is to be found only in restoring the integrity of the cervix by trachelorrhaphy.

Those lacerations which have been apparently perfectly healed by caustics and astringents, or in which Nature has repaired the rent so far as she could by glazing over the raw everted surfaces with a delicate cicatrix, not unfrequently disappoint patients and physicians by causing the same annoying bloody oozing described above, as springing from eroded granulations. Here the surface is perfectly smooth, the os small, and no cervical catarrh present; but scattered over the pale, dull pink surface of the everted lips are seen several small dots or patches of a bright red color, which bleed on being touched or wiped with cotton. These are merely spots of cicatricial tissue which have broken down, as such tissue is liable to do if exposed to friction or bruising. That the epithelium has disappeared from these patches is shown by their turning white when a solution of nitrate of silver is applied to them, while the neighboring sound surface remains unchanged.

These are the cases which have been "cured" by those physicians who do not believe in the operation for laceration of the cervix. In my paper, already referred to, on "The Indications for Hystero-Trachelorrhaphy," I refer to the merely temporary character of this form of "cure," and give a colored plate illustrating the breaking down of a cicatrized laceration, which was taken from a case of spontaneous healing. Recently I have met with two typical cases of this occurrence in patients who had been treated in the non-operative manner by prominent opponents of the operation.

CASE II.—A lady consulted me during the past autumn for a prolonged menstrual flow, saying that four years previously she was delivered of her only child, and from that time on had been under treatment. In the first place, the bloody lochia continued unusually long and were very profuse; then she suffered a great deal from leucorrhœa, and her menstrual period was prolonged from four and five to ten and twelve days. At irregular intervals she would flow very profusely; but generally

about a week before the expected return of the period she would begin to ooze moderately, merely sufficient to soil her clothes and annoy her, until the regular flow came on. She was under the treatment of a prominent gynecologist of this city for three years, who, she says, cauterized the "ulcerated womb" frequently, giving her a great deal of pain, and after a few months of treatment she would improve, the menorrhagia and premenstrual oozing would cease, and treatment would be discontinued. But in a few months the same oozing would return, again to yield to treatment, and this rotation continued for about three years, when the lady decided to try a trip to Europe. There she consulted a prominent German gynecologist of the old school, who told her she had an ulceration, treated her by caustics, and discharged her cured. She returned to this country last September, apparently well, but in November the old bloody discharge again preceded the expected menstrual flow, and the lady consulted me. I expected to find an erosion, but my finger detected a double laceration, and the speculum showed me two everted lips glazed over, with six to ten raw, readily bleeding spots in them, varying in size from a pin's head to a pea. A sound passed into the uterus produced no bleeding. There we had the source of the stillicidium, and the explanation of the failure of either of the two prominent gynecologists to effect a permanent cure. Neither of them had told the lady that her cervix was ulcerated. Of course it is not to be supposed that they failed to recognize the rent; but the New York gentleman, while a skilful and bold operator, has chosen to deny the necessity for the operation of trachelorrhaphy, and the German, I presume, has retained the conservative ideas of his youth. My opinion was verified a week later, when the lady reappeared, the usual oozing having just begun. Exposing the cervix at once without touching it with the finger, the blood was seen oozing in drops from the eroded patches; none, as yet, came from the uterine canal. The remedy was obvious, viz., to heal the erosions (as had so often been done before), and then keep them healed by turning the everted cervical mucosa back within the cervical canal, and retaining it there by the operation of trachelorrhaphy.

CASE III.—A dispensary patient, a multipara, was told by me several years ago that the menorrhagia and leucorrhœa of which she complained could be cured only by the repair of her lacerated cervix. She dreaded the operation, and I lost sight of her until a few weeks ago, when she called at the Polyclinic, complaining of the same symptoms. She stated that she had been under the care of a prominent gynecologist, who took her into his service in a celebrated New York hospital, and treated her by astringents and tampons for two months, with the result of improving her condition, but finally admitted that to cure her completely without an operation would require a long time, and discharged her. It should be mentioned that this gentleman is also an adversary of Emmet's operation, and that, before consulting him, the woman sought the advice of the same gynecologist referred to in the previous case, who told her that no operation was necessary. I found the cervix in its old state of laceration of the third degree, with complete eversion; the eroded surface much smaller, it is true, but still sufficiently large and raw to bleed on digital examination.

Here we have two instances of long-repeated, persistent efforts to heal over permanently the eroded surfaces of a torn cervix, with the result of but temporary improvement in each case. The cases are both instructive as to the origin of the bleeding and its permanent cure. I am sure both cases could have been cured years ago if the proper treatment by trachelorrhaphy had been adopted. I have chosen these two cases from many similar ones, because they illustrate so well the uselessness of palliative treatment for hemorrhage depending on cervical laceration.

3. *Chronic subinvolution of the uterus* is a very common result of abortions, of long, tedious, and instrumental labors, and of lacerations of the cervix. One of the prominent symptoms of this condition, besides pelvic pain and weight, bearing down and backache, is profuse menstruation. In such cases the uterus is enlarged, soft, pulpy, and the blood appears to ooze from it as water does from a wet sponge when it is squeezed. I have frequently searched the cavity of such uteri with the dull curette, expecting to find granulations or remnants of placental villi, and have been disappointed at not removing anything but a few shreds or streaks of bloody pulp. Such women often bleed *very* profusely at their periods, and require all the inter-menstrual time to recover from the loss. In course of time this recovery grows less and less complete, and the patient becomes thoroughly anæmic. I have found constitutional treatment alone to give but slight benefit in these cases. Ergot, diluted sulphuric acid, viscum album, etc., have temporarily checked the flow, especially if rest and ice were likewise employed. But in several such cases only the tight tamponade of the vagina, repeated day after day, succeeded in finally arresting the hemorrhage. My method of treating these cases is to make applications of Churchill's tincture of iodine to the endometrium twice a week during the inter-menstrual period, taking care to make the application thorough by repeating it at the same sitting until any oozing of blood, which may possibly occur, ceases. The usual hot water injections are taken twice daily. These iodine applications should be continued up to the very inception of the flow. I have seldom failed to keep the hemorrhage within bounds by this treatment, which I have always practised at my office. I also give a pill of ergot, gr. j.; sulph. iron, gr. ij., and strychnine, gr. $\frac{1}{60}$, three times daily.

If the flow should still be too profuse, I put the patient to bed, and after four or five days do not hesitate to check it by the iodine application and firm tamponade, repeated daily until effectual. At the same time I give rectal suppositories of ergot, three to five grains each, three times daily. In a few cases the fluid extract of viscum album, in teaspoonful doses every two or three hours, has kept the flow in bounds.

Patient and physician should remember that usually several months of the above treatment will be required to insure a permanent benefit or a certain cure. If proper precautions are observed, as to rest for the remainder of the day after an application has been made and as to avoidance of exposure to cold, this treatment can usually be considered safe and harmless. The applications are made by cotton-wrapped hard rubber applicators, if the uterine canal is patulous (as it generally is in subinvolution and menorrhagia), or by the syringe-applicator (the syringe being first filled with tincture of iodine, the nozzle wrapped with cotton, and the fluid gently expressed into the cotton after the nozzle has been passed to the fundus) if the canal is of moderate calibre. The usual protective tampons are inserted for twenty-four hours. If the effect is to be a very decided one (as during the flow), I make the application by the slide-applicator, slipping the saturated cotton off and leaving it in the uterus, to be removed by a twine attached to it with the vaginal tampons. When the uterine cavity is tamponed in this way, absolutely no hemorrhage can take place. It is in this variety of uterine hemorrhage that I find intra-uterine medication (of whatever character) the most beneficial.

4. *Hemorrhage from chronic hyperæmia of the uterus.*—In a certain number of women, a profuse menstrual flow seems to depend on nothing but a chronic congestion of the uterus; at least the examining finger can detect no enlargement or other cause for the excessive flow, and the sound elicits more or less hemorrhage. I dare say an excessive friability of the vessels of the uterine mucous membrane may also be the cause of this hemorrhage. I have found this variety chiefly in young unmarried or in

married but nulliparous women. Ergot seemed to exert but little influence over it, but the iodine applications above described were invariably effectual. I have never had to practise them in this form at other than the inter-menstrual time, and a few months of treatment have always cured the case. Of course, we should remember that in some women profuse menstrual flow is physiological, and that then it should not be interfered with; but when the flow entails anæmia and debility, it needs active treatment for its control.

5. *Prolonged menstrual flow from retention of blood by flexion or pinhole external os.*—As a rule, when the normal menstrual flow has reached its termination, a period variable in every woman, the discharge of blood ceases, and merely a slight sero-mucous oozing continues for a few days. Until the next regular epoch the healthy woman has no discharge whatever from her genitals; but in a few instances I have been consulted for a return of the bloody discharge, from several days to a week after the apparent cessation of the flow, this discharge continuing for several days, and alarming and annoying the patient. In one case this recurrence of bloody discharge took place at irregular intervals during the month. In no case was the amount of blood lost sufficient to debilitate the patient, nor was this the reason for alarm, or for her seeking professional advice. The cases were all in unmarried or young married women, who had never been pregnant, and all ladies of refinement, who were particularly careful about their persons and whom this oozing annoyed. The color of the blood was always spoken of as being dark, and mention was made that it seemed to issue in gushes, small clots, preceded by pain of an expulsive character.

An examination in these cases would show one of two conditions: first, and most commonly, a small, "pinhole" external os, with dilated cervical canal, and, second, a retroflexion, with normal uterine canal. The explanation of the secondary menstrual hemorrhage complained of in these cases seemed perfectly simple. In the case of the narrow external os, the menstrual blood, which toward the close of the period exudes less rapidly, is prevented by the narrow orifice from escaping freely, coagulates in the cervical cavity, and is gradually expelled in gushes or coagula, several days after the supposed complete cessation of the menses. This is, of course, not properly a profuse menstrual flow, but merely a prolongation of the natural period.

The treatment of this case is perfectly simple. Remove the obstacle to the free discharge of the blood, make the whole uterine canal of equal width, and the menstrual blood will escape from the external os as it is poured out into the uterine cavity, and all discharge will cease as soon as no more blood is exuded. This is best done by making a so-called crucial incision of the external os, dividing the mucous membrane covering the cervix to the length of about one-fourth of an inch, and then trimming off each little flap with fine curved scissors, so as to make the external os funnel-shaped. Then, by stretching the uterine canal with divergent dilators, and, if thought advisable, swabbing it with tincture of iodine, this little operation is completed. Dilatation once a week for several weeks, or even several months, is essential to prevent the orifice from contracting again, and the iodine application may be repeated once or twice, if there be a hemorrhagic tendency in the endometrium.

This treatment resembles very much that necessary for chronic cervical catarrh, only that the latter needs much more active caustic treatment and is more intractable. In the case of retroflexion, it is evident that the last blood exuded at the close of the period is not sufficient to force its way up and through the angle of flexion, for the very simple reason that blood, no more than water, will flow up hill. Finally, when the uterine cavity is full the overflow takes place, or the uterine body reacts on the foreign contents and expels them by contraction. Hence the pain complained of. By elevating the fundus

uteri by a well-fitting pessary, and in addition straightening the canal by dilatation, this retention of blood will evidently be rendered impossible, and any chronic hyperæmia of the endometrium, which may exist besides, is easily remedied by repeated applications of tincture of iodine.

Both these conditions are readily susceptible of cure by the methods above described.

There is one other form of uterine hemorrhage which I had intended to speak of, namely, that caused by the pelvic congestion induced by a large cellulitic exudation. But this article has already surpassed the bounds originally set for it, although I have purposely avoided citing numerous cases in illustration of my remarks, and I shall be compelled to defer a further consideration of this subject to another occasion.

While the uterine hemorrhage treated of in this paper rarely, if ever, assumes alarming proportions, still its persistence and frequent recurrence renders it a subject of alarm and annoyance to the patient, and therefore of etiological and therapeutical interest to the practitioner.

ON THE INJUDICIOUS USE OF THE SULPHATE OF QUININE.

By D. B. St. JOHN ROOSA, M.D., LL.D.,

NEW YORK.

In a paper read before the New York Neurological Society in 1874,¹ the writer of this article called the attention of the profession to the possible dangers to the organ of hearing from the administration of quinine. Some discussion arose upon this suggestion, for the remarks involved scarcely more than a suggestion at that time. This discussion led to a series of experiments conducted on the living human subject by myself, and upon animals by Dr. Wm. A. Hammond. The outcome of these experiments showed that the administration of the sulphate of quinine, in doses of from ten to fifteen grains, appeared to cause vascular injection of the auricle, auditory canal, the drumhead, the conjunctiva, and possibly of the optic papilla, although the latter point was not so strongly insisted upon, the evidence of support being based upon one case.

Besides these objective symptoms, which were well marked in four of the five subjects experimented upon, there was decided tinnitus aurium and exhilaration, the latter being apparently like that from a glass or two of champagne. A case of otitis, which was apparently caused by the use of quinine, and which has elsewhere been reported in full, turned my attention to this subject as early as 1870.² I have also reported³ a case where impairment of hearing already existing was greatly increased on the use of quinine, even in moderate doses. That the use of the drug does this in many cases I have been able to verify from frequent experience. It is particularly harmful to ears that are already in a state of hyperæmia or congestion.

Subsequent clinical investigation have placed the fact beyond doubt that it is not entirely uncommon to see inflammation of the retina or its blood-vessels and also of the middle and internal ear following the administration of large doses of this drug. The cases to illustrate this point are too numerous to be explained away, and I believe that argument has ceased against the credibility of the belief that the primary effect of moderately large doses of sulphate of quinine is a congestion of some parts of the ear and of the retina. There remain a few who deny that the effects of quinine are anything but evanescent, but the cases published first by myself,⁴ and subsequently by Voorhies, De Wecker, Gruening, Buller, Knapp, and others have finally set-

tled the point that in rare instances deafness and blindness may be caused by large doses of quinine. Dr. Baldwin, of Alabama, has also published a pamphlet, not at this moment accessible to me, in which he has shown the dire results that have sometimes occurred from the injudicious administration of quinine, especially in our Southern States.

I am far from saying, that in some of these cases, where the quinine was administered, for serious disease, it may not have been necessary to take the chances of ruining the sight or hearing. I simply wish to call the attention of the profession to the fact, that such a peril may be incurred. I believe, however, that this drug is sometimes administered in diseases where its effects are harmful, and only harmful. Such a disease is, I think, pyæmia. Dr. Edward T. Ely¹ and myself treated a severe case of this disease, without the use of quinine or of any other drug, and recovery ensued.

I believe that in similar affections in which quinine is generally administered it may be unnecessary, injudicious, and possibly dangerous.

I have taken great pains to avoid any undue exaggeration in the language which I use, for I know very well that the use of the sulphate of quinine in reducing temperature, in diseases where increase of temperature is a symptom, and the breaking-up of catarrhs, is firmly fixed in the minds of many practitioners as the one means of treatment to be at once seized upon. So strongly has the conviction of the almost panaceal properties of quinine come to the minds of the profession that there are hundreds of families in New York City, in which large doses, that is to say, ten to fifteen grains, of the sulphate of quinine are taken with no more provocation than the apparent coming on of a serious cold in the head. Now, I believe that quinine, given under no advice except that of the family of the patient, is a dangerous drug. I am behind no one in my appreciation of its value in appropriate cases, and I should certainly regard unmistakable malarial fever as an appropriate case, or intermittent neuralgia, and all diseases with a well-marked malarial type. That there is some abuse of the term malarial, however, perhaps all of us are ready to admit.

I am sometimes called to see cases of diseases of the ear, occurring in the course of the exanthemata, during convalescence usually, or at least during the middle stages, and I so often find that the symptoms are aggravated, in my opinion, by the administration, even to young persons, of ten to fifteen grains daily of the drug, that I have felt it my duty to go over this subject and bring to the mind of the profession these apparently forgotten facts concerning the effects of quinine, facts which I claim to have been largely instrumental in bringing to the mind of the profession. The effects of the sulphate of quinine in pyæmia, for example, are quite contrary to what we desire in the cure of that disease, if cure can be accomplished. If its cure is to be by elimination of the poison through the bowels, through the skin, and through the kidneys, quinine has for one of its chief actions the shutting up of these excretories, and is therefore in the opinion of some, of whom I am one, just the drug which is absolutely unfitted for the conditions. For the throwing off of the poison constituting pyæmia, the skin, kidneys, and bowels should be unclogged sluice-ways. This they cannot be in a patient fully under the influence of quinine. It seems as if a rapid reduction of temperature is considered the one thing desired by some practitioners in all cases of fever. None of us will say that this reduction by the use of a drug should always be sought for. How many patients die all the same, although the quinine "brought the temperature down!" There may be a natural reduction even of a temperature of 104°, and this may be in some cases at least more desirable than one induced by medi-

³ The Medical Record.

⁴ Archives of Ophthalmology, vol. viii., p. 392; vol. ix., p. 41.

¹ Archives of Otolaryngology, vol. x., page 42.

cine. Certainly I recall one case where the sudden reduction of the temperature only hastened the fatal collapse. It is no light matter to bring down the temperature with such rapidity as large doses of quinine will sometimes do. Again, a cold in the head and congestion of the nasal cavities and of the frontal sinuses, I believe, are aggravated by doses of quinine sufficient to cause any appreciable effect.

I well remember a case, which I saw about a year ago, occurring in the family of one of my relatives, where a delicate woman had been seized with a severe naso-pharyngeal catarrh just after a long railway journey. She suffered excessively from the neuralgia arising from the congested frontal sinus, and naso-pharyngeal tract. Instead of what I regard as appropriate and anodyne treatment, in a warm room, to which she should have been confined, she was kept about the house, and drugged by her family with quinine until the *tinnitus aurium*, the fulness of the head, the nervous irritability often caused by it, added to the symptoms of the catarrh, made the patient a pitiable object of suffering. When the quinine was stopped, and warm fomentations applied over the frontal sinuses, the throat kept clean by the use of the chlorate of potash, the symptoms began to be at once ameliorated.

The very day that I was engaged in looking over this paper for revision, a gentleman who occasionally consults me in regard to a chronic inflammation of one of his ears, came to ask my advice about a cold in the head, and *tinnitus aurium*. His first remark was, "I took ten grains of quinine when I found this thing coming on, but it has made my ears ring so that I feel much worse." This practice of taking quinine to abate colds has good authority to back it, but in the face of such authority I interpose my objection that in all colds affecting the mucous membrane of the nares, Eustachian tubes, and tympanic cavities it aggravates the condition, and is therefore a bad remedy.

In diseases of the ear it becomes positively harmful by increasing the congestion which already exists. I have seen cases of subacute disease and acute disease of the ear which immediately began to recover as soon as the use of quinine was stopped.

Whenever a drug, as powerful and dangerous as quinine, becomes the property of the laity, we may expect to see abuses from its use. There never yet was a popular error with regard to medical subjects which cannot be traced, in my opinion, to indiscreet practice on the part of ourselves. It is very dangerous practice to allow the public to prescribe for themselves. I ask the profession to review this subject of the administration of quinine in cases not malarial in character. I believe that they will then determine that its value in any other than such cases is doubtful. In diseases of the ear it is especially harmful, as it may be in those of the eye, especially in large doses. As used for the elimination of poisons, I believe it to be dangerous and harmful. For the so-called simple maladies, such as colds in the head, its use is generally attended by aggravation of the symptoms, and may cause them to extend to the ear. Its efficacy in malarial affections remains, however, indisputable. In severe cases of fever with this type, I suppose we are justified in taking the slight risk to the organs of sight and hearing which its use in large doses may involve.

AN INGENIOUS DEVICE FOR SUPPORTING A HOSPITAL.—Mr. Arthur Keugh, of London, has hit upon an ingenious plan for getting funds for the Dental Hospital. He has started a "cigar thrift fund." He places boxes in cigar shops, clubs, smoking-rooms, etc., in which the ends of cigars can be placed. They are valuable enough, if the system is sufficiently widespread, to bring in a considerable sum of money annually. There is also a small cigar-cutter for the waistcoat pocket which preserves the tips, and these gentlemen themselves can save and forward.

SOME QUESTIONS RELATING TO TONSILLOTOMY.

By W. H. DALY, M.D.,

FELLOW OF THE AMERICAN LARYNGOLOGICAL ASSOCIATION; PHYSICIAN FOR DISEASES OF THE THROAT AND LUNGS TO THE PITTSBURGH FREE DISPENSARY, PITTSBURGH, PA.; SENIOR PHYSICIAN TO THE WESTERN PENNSYLVANIA HOSPITAL, PITTSBURGH, PA.; EX-PRESIDENT OF THE ALLEGHANY COUNTY MEDICAL SOCIETY, ETC.

A BRIEF discussion of some of the questions involved in the operations for the removal of the tonsils, from a practical standpoint, will be the aim of what we have to say to you, and in order to arrive at some rational conclusions, we will give some of the views, based upon a personal experience with a large number of cases, as well as some of those arising from consultation, with authorities, who by their observation and experience are calculated to give intelligent opinions upon the questions as follows:

- I. The question of the operation itself.
- II. The question of hemorrhage after tonsillotomy.
- III. The question of the operation affecting the physical growth.
- IV. The question of virility being affected by tonsillotomy.
- V. The question of the voice as affected by the operation.
- VI. That of faucial utility.
- VII. The question of sleep.
- VIII. The question of the tonsils becoming again hypertrophied after their removal.

I. Without entering into the anatomical details as to the structure of these glands, we will deal more particularly with those phases of the first question* which most concern the utility and propriety of the operation itself. As regards its antiquity, there is none more honored than tonsillotomy,¹ and as to the methods there is scarcely an operation spoken of in the annals of surgery that has excited more human ingenuity with a view of increasing the practicability of its performance,² and hence there are a diversity of plans. However, the busy practitioner or specialist is most concerned with what is the best mode of operation, the indications for its performance, and a knowledge of some of the dangers to be avoided. Of one thousand cases collated at the London Hospital for Diseases of the Throat all but thirty-one were observed and operated upon in persons under forty years of age, and the period between ten and twenty years is the one in which more than one-third of the cases³ were seen and operated upon.

In patients suffering from enlarged tonsils the bodily powers are often feeble, some of them congenitally so. Others have derived cachectic constitutions from scarlatina, with throat complications, or from repeated attacks of quinsy, or have inherited a tendency to scrofula or tuberculosis.

It has also been thought by modern observers that patients with enlarged tonsils are not altogether free from the rheumatic diathesis. Be the causes whatsoever they may, we cannot but assert that the child which presents the peculiar stupid countenance, with the open mouth, drooping eyelids, dull expression, thick voice, and the profound impress of constitutional impairment, as well as intellectual dulness and morbidness of disposition, so generally seen in those suffering from hypertrophied tonsils—be the differences of professional opinion ever so varied as to the several questions noted, at least there is an urgent demand for operative interference, in order that the life of the patient, both waking and sleeping, may be more comfortable, and that the organs of deglutition, respiration, and vocalization may do their work unimpeded, and that the vitality of the growing child may assert itself, as it is sure to do after being freed from the constantly impending danger and distress of follicular tonsillitis and congestive pharyn-

¹ Mackenzie: Diseases of the Larynx, Pharynx, and Trachea, p. 52.

² Op. cit., p. 53.

³ Op. cit., p. 46.

gitis, with all the other attendant obstructive discomforts, which are so apt to follow the slightest exposure to atmospheric changes.

The presence of enlarged tonsils ought to be sufficient reason to demand their removal, but there are other considerations that increase the need for interference with them.

The breathing is often obstructed to such a degree as to become noisy during waking hours, and little children so afflicted snore during sleep like strong grown men, owing to the posterior nares and pharyngeal cavity being blocked up by the mass of tonsillar tissue on either side.

Interference with the sense of hearing is a rather common result of enlarged tonsils, but is not so much due to mechanical obstruction of the Eustachian orifice by the tonsillar growths, as to a general thickened condition of the pharyngeal mucous membrane, the result of inflammatory hyperplasia. Michel¹ has shown that this form of deafness is often due to the pressure of Luschka's tonsil upon the posterior lip of the Eustachian orifice.

The obstruction to free nasal respiration from enlarged tonsils exposes the patient to all the influences which tend to bring on inflammation of the air-passages.

In 1828 Dupuytren called attention to the frequency with which deformity of the chest was associated with enlarged tonsils, and the so-called pigeon-breast is often associated with the same condition.

Chassaignac² well observed, "that although increased efforts of the diaphragm to a certain extent neutralizes the impediment to respiration from enlarged tonsils, there are frequent intervals when the powers of the muscles become temporarily exhausted, and the oxygenation of the blood is very incompletely performed. The vital forces are in consequence very much lowered and the patient lives in a state of permanent ill-health and easily succumbs to any acute attack of disease particularly affecting the respiratory organs." This writer also mentions several cases to illustrate the evil effects of the disease on the brain, the digestive organs, and on the senses of sight, taste, and smell. He thinks the pressure of the enlarged glands obstructs the flow of blood to the brain, and impedes its return, whilst the digestive organs suffer when there is difficulty of swallowing.

Mackenzie³ has often observed that the senses of smell and taste are defective in the subjects of enlarged tonsils if the disease has existed for any length of time. This I have also observed in a few well-marked cases.

As this paper is not intended to treat of the medical applications recommended for enlarged tonsils, though there are many used, but in my own hands most of them have proved very tedious and unsatisfactory, we will, therefore, speak of some of the most approved operative procedures, and among these ought to be mentioned the various caustics, viz., the nitrate of silver, chromic acid, nitric acid, the acid nitrate of mercury, and the galvano-cautery. Most of these are regarded in some respects as safe remedies, but some of the caustics are liable to do unlooked-for mischief by dropping into the larynx, or they may do injury to the eyes of the operator, as I have once known to occur from the patient coughing some of the caustic application into the operator's eyes. The galvano-cautery has lately been used to destroy the enlarged tonsils, and few specialists there are who are familiar with the use of this battery who have not used it to a greater or lesser extent for this purpose.

Dr. Cohen, of Philadelphia, has used this method of removing them, and seems to be favorable to its employment in certain cases. The advantages regarding its use, are safety from hemorrhage, but the disadvantages attending it are several. The inflammation following its employment is often severe. The slough is never just what is expected. It is either more or less than desired, and during the operation there is the dis-

agreeable odor of burning flesh that few patients will tolerate more than once, and still fewer will permit longer than a few moments. The stump left after this method is often unsightly, and too often hard and of the nature of the cicatrices of burns.

This plan, as well as that by means of electrolysis will scarcely ever become popular with practitioners, and the same methods are destined to be decidedly unpopular with patients, at least this view is in accordance with my own experience. Hence I have a very decided preference for the cutting operation; and to perform it with ease, one assistant should always be present, and if he has had experience all the better. One of the best I have ever had was a colored groom, who not only seemed to have an aptitude for assisting in this operation, but a fondness for witnessing the flow of blood.

The patient being placed in a good light, either artificial, which I prefer, or the sunlight, which is quite as good, if not better, the assistant should support the head of the patient against his breast or stomach, and with the ends of the fingers make compression steadily and carefully beneath the angle of the jaws on each side to steady the head of the patient, and press the tonsils into the throat. The operator takes his place in front of the patient.

The guillotine is the best instrument for the operation if the growths are not too large to enter the fenestrum. The one I prefer is that of Professor Physick, of Philadelphia, as modified by Morell Mackenzie, of London (Fig. 1). With this instrument, a firm grasp can be had

Fig. 1.

upon its handle, with which to hold it in place while operating.

The guillotine of Dr. Wm. B. Fahnestock, of Lancaster, Pa., is perhaps better known throughout the world, and more modifications have been made upon its original pattern than any other guillotine.

Guersant, Velpeau, Chassaignac, and Maisonneuve all made important modifications of it, and it is probably the instrument most used by surgeons everywhere.

The Physick guillotine being ready for use, the hilt is grasped in the left hand, and with the index finger of the right hand, the right tonsil of the patient is sought, and surrounded by the fenestrum. Some pressure is made by the guillotine as well as by the assistant, that the growth may be encircled well to its base. Then the knife is with the thumb of either hand pushed quickly home. The tonsil is usually brought away in the instrument, having caught by some shreds in the sulcus or slit which receives the knife.

I prefer to operate with the left hand first, as in case of any unruly behavior on the part of the patient, the dexter hand remains to do the operation on the other tonsil quickly. The entire operation can be done quickly and is usually painless.

When the growths are either too large to be easily removed by the guillotine, or when they are like a narrow

Fig. 2.

flap projecting into the throat, I then use these laterally curved knives with long handles, which were devised by myself (Fig. 2), and I have found them efficient, the part

¹ Krankheiten der Nasenhöhle, Berlin, 1876.

² Bulletin Générale de Thérapie Médicale, 1843.

³ Op. cit., p. 49.

to be removed, being seized by these vulsellum forceps (Fig. 3) or this tenaculum (Fig. 4), and any other nodular growths about the tonsils can as readily be removed with them.

With reference to these laterally curved-bladed knives,

Fig. 3.

which have probe points, as you see, and long slender handles, I may say that they are probably only a modification of knives used before by others; but in my search after something to suit my purpose in these operations, I was unable to find anything in the many illustrated catalogues of instruments that met my own ideas of what I desired. These I have found to answer the purpose

Fig. 4.

admirably. I can safely assure any one who desires to use them, that they will do the work neatly and satisfactorily. They were made for me by Otto Helmold, instrument maker, Pittsburg, as modifications of one I had made by Tiemann, of New York, which is, as you see, rather large for the purpose for which it was designed.

My friend, Dr. Pollock, of Pittsburg, years ago used a curved-bladed knife in these operations, such as I show you, and while either instrument will do the work there is yet a vast difference in the construction of the two knives.

II. The question of hemorrhage after the tonsillotomy is one that every operator should be fully prepared to meet at once. I am lately in the habit of having beside me a pair of torsion forceps (Fig. 5), such as these, to

Fig. 5.

twist any artery that may emit too much blood. I also like to have a galvano-cautery battery ready for use, with a pharyngeal knife attached to the handle, in order to arrest hemorrhage, which may be copious and persistent from blood-vessels too minute to be seen with the naked eye. Indeed, the most alarming case of hemorrhage I have ever seen after this operation was in such a case; the patient became so weak from the loss of blood that he was neither able to stand nor sit.

It is true, a simple gargle of alum-water or tannin will most generally suffice, and either iced or very hot water as a gargle is quite equal to control most of the cases of hemorrhage that will occur, but to be prepared for emergencies is to only be guided by good judgment.

A case of hemorrhage after tonsillotomy was related to me by a medical man that contains such a valuable lesson that it is worthy of repeating here. He had an appointment to remove the enlarged tonsils of a farmer's boy, but when he punctually arrived, ready to operate, the boy had reconsidered the matter, and thought it wise to be away after the cows. The doctor, not to be outwitted by the boy, drove after him, and at length found him with the cows some distance from the house, on an out-of-the-way roadside. After some persuasion the boy finally assented to the operation being done on the spot. One of the tonsils was seized and removed by the guillotine, but the hemorrhage which immediately followed was so copious and alarming as to compel the medical man

to keep his fingers on the stump of the gland for several hours before any one happened along, in order to get assistance and save the patient's life. This operation was not performed soon again by that medical man, and when he did so, he secured a more auspicious occasion and surroundings for the work.

Dr. Morell Mackenzie says he has "only known of one case when hemorrhage actually seemed to endanger life out of the one thousand cases reported." Velpeau reported four cases of laying open the internal carotid artery in operations for the removal of tonsils.

I once had a case of serious tonsillar hemorrhage recurring two days after the operation, from the patient having attempted to eat solids, contrary to instructions.

III. The question of the operation for the removal of enlarged tonsils affecting the physical growth of children, may be briefly stated in my own experience to have always been most positive and flattering in the highest degree; so much so, that I have no hesitation in assuring the friends of the patient that they may look for improvement in the physical status of the child, and I have never yet been disappointed, especially so if proper treatment is carried out with reference to the cure of concomitant catarrhal disease of the naso-pharynx.

IV. Now as to the fourth question, viz., that of the virility of the individual being affected by tonsillotomy,¹ I have a very firmly fixed opinion that there is no more intimate or special relationship existing between the tonsils and the testicles and their functions, than there is between the hair on the scalp of the patient or the teeth and the testicle.

The recent revival of this question is chiefly due to a lecture delivered some months ago by Professor R. A. F. Penrose, of the University of Pennsylvania, in which his words, as quoted, were somewhat in this wise: "I some time ago asked a professional friend of mine, who was in my office," said the professor, "if his experience and observation would lead him to believe that the excision of tonsils had the effect of destroying the virile power in the male? He assured me it had no such effect. 'Why?' said he, 'I had my own tonsils excised when I was young.' Now, gentlemen," said Professor Penrose to his audience, "that man's wife had no children." Will you not allow me to mildly indulge in sophistry by saying that a man may have lost a toe, or a finger, or a nose, and his wife have also failed to bear him any children; it does not follow, however, that had some other woman been his wife that he would have been similarly childless, neither is this illogical assertion proof that the medical friend of Dr. Penrose was childless, although his wife bore him none. In answer to a communication to Dr. Penrose, a few days ago, I received a reply which contained the following: "The lecture (meaning the one above referred to) was published unknown to me in some obscure New York journal. Since then I have received several communications from medical men of cases where removal of the tonsils did *not* prevent procreation."

It is to be inferred from this that Dr. Penrose is not altogether prepared to say his position has been strengthened by the testimony of the profession, and as the most striking example cited by the doctor was the one case of his medical friend, it is scarcely necessary to pursue this side of the question further; but as to the opposite view, I will state that Dr. G. F. McC—, of Pittsburg, informs me that he had tonsillotomy performed when a child. He is now the father of two healthy children, and he, as well as his wife, are still young. Dr. Wm. Wallace, of Pittsburg, informs me of a friend of his, G. W. H—, who was operated upon for enlarged tonsils when a child, who is now the father of three children.

Dr. John Dickson, of Pittsburg, whose name as an able and experienced surgeon was a household word in

¹ British and Foreign Medico-Chirurgical Review for 1860.

Western Pennsylvania even before many of us were born, expressed to me his opinion that the excision of the tonsils had as little to do with the power of procreation as the excision of the toe-nails, and he cited the instance of A. B——, now of Alleghany City, whose tonsils he excised many years ago when the present man was a child, and who is now the father of a large family of healthful children. He also spoke of the wife of Dr. Wm. M——, of Beaver, upon whom he operated, and who has since been the mother of several children, as also one of the present daughters-in-law of the doctor, whose tonsils he excised when she was a child, but twelve years old, who has since been the mother of three children.

Mackenzie, one of the closest and most careful observers, as well as one who has had probably greater opportunities for observation than any other man who has practised as a specialist of throat diseases in any period of time, says only this, "The disease not unfrequently becomes developed for the first time about the age of puberty, owing, as *some suppose*, to a sympathetic connection between the sexual organs and the tonsils,"¹ and he says further, "Probably many of the cases in the earliest period were either congenital, or made their appearance soon after birth." In a conversation some time ago on this subject with the accomplished laryngologist, Dr. Elsberg, he expressed to me the opinion that there was no relation whatever between the operation of tonsillotomy and any subsequent loss of will-power.

V. The question of the voice being affected by the operation. It cannot be denied that the muffled or thick voice disappears sooner or later after the parts have healed.

VI. The faucial utility is much enhanced as the sense of the presence of a foreign body is no longer a source of annoyance, and the act of deglutition is performed with ease and comfort.

VII. The question of sleep. That repose is no longer disturbed by obstructive suffocation which patients complain of, is a matter of fact, and refreshing natural sleep, unaccompanied by noise or snoring, is productive of rest and recuperation.

VIII. As to the question of their liability to grow again, the answer can be included in the remark, "that with every badly treated or neglected cold affecting the throat, there will be some tendency for them to increase in size again, but the tendency is not marked by any means, and may be prevented altogether with ordinary care and proper treatment by local applications.

It is a matter of observation that enlarged tonsils have a tendency to subside after the age of forty years has been attained.

WOMEN DOCTORS IN SPAIN.—*La Tribuna*, of Madrid, has a long account of the granting by the medical faculty of that city of a Degree of Medicine on Señorita Martina Casella Bellaspi. She is the first Spanish woman who has studied medicine and taken her degree. The paper speaks in warm terms of her as a lady who, in spite of much opposition and national prejudice, has won high honors. Another Spanish lady is following in Señorita Bellaspi's footsteps. Finding that the Valencian School of Medicine had closed its doors against her, she is now studying in Madrid, where she has met with a more friendly reception.

THE RIGHT NAME.—The title of the new journal, *The Undertaker's Assistant*, may be objected to on the ground that it is ambiguous. *The Toy Pistol* is suggested as a substitute by *Harper's Weekly*. Perhaps *The Lancet* or *New Remedies* would do.

URETHRITIS CAUSED BY FROGS.—Dr. Bonarny, in a recent thesis (*Rev. de Therapeut.*, No. 19), describes two epidemics of urethritis among soldiers in Africa, caused by eating frogs which had fed upon cantharides.

Reports of Societies.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

Seventy-seventh Annual Meeting, held in Albany, February 6, 7, and 8, 1883.

TUESDAY, FEBRUARY 6TH — FIRST DAY — MORNING SESSION.

The Society met in Geological Hall, and was called to order at 10 A.M. by the President, DR. HARVEY JEWETT, of Canandaigua.

Prayer was offered by REV. ALBERT FOSTER.

The inaugural address was delivered by the President and referred to a special committee, to be appointed by the Chair.

THE PRESIDENT'S INAUGURAL ADDRESS.

With pleasure and great cordiality the President greeted the Society on the return of its Seventy-seventh Anniversary Meeting, for the discussion of scientific subjects and strengthening the social and fraternal ties of the profession. He made his grateful acknowledgment for the high compliment of an unanimous election to the presidency of the largest medical society in the United States. Brief reference was then made to the progress in every department of literature and science which characterizes the present age. Speaking of the medical profession, he said:

"The result of all legislative enactments in this, and I believe in other States, for the last forty years, to regulate the practice and elevate the standard of medical education, has done little or nothing to abate quackery or increase the interest in the medical literature in this State. Whatever is done in regard to this subject must be done by the profession through their individual organizations. The profession is competent, through their representatives in the State and County societies, to establish what shall be the standard of attainments of those who are to be received into their ranks. A more complete and thorough preliminary education of young men who desire to enter upon the study of medicine is the first step in advancing the cause of medical science. A much higher standard of medical qualifications before the granting of a diploma is universally conceded and acted upon by the leading medical colleges in this country. These requirements, if carried out, will in the future tend to bring about the desired result. We have, as a nation, reached a stage of progress and development when our leading medical schools can carry the standard of professional education to a much higher plane than in years that are past."

Dr. Jewett then urged that the law of 1872 should be made mandatory, and that a State Board of Examiners, appointed by the Regents of the University and the Medical Society of the State, entirely disconnected from the schools, and whose certificate alone shall be a passport for graduation, would remove all imputation of partiality or favoritism from any source.

"All medical schools that fail to come up to the required standard of instruction" will go down for want of patronage, and we shall see illustrated the doctrine of evolution in the "survival of the fittest."

The recommendations of his predecessor in relation to the establishment of separate hospitals in our large cities for the isolation and care of those who are suffering from contagious diseases, such as scarlet fever and diphtheria, as well as the humane supervision of factory children, he regarded as eminently philanthropic and demanded considerable attention at the hands of this Society.

The subject of the adulteration of food and drugs received reference.

The President also respectfully suggested that the annual address of the President be delivered in the hall

¹ Crisp and Headland, Dublin Med. Press, vol. xx., p. 229, 1849.

where the daily sessions were held. He also directed the attention of this Society to the efficient and philanthropic labors of our State and National Boards of Health, and hoped that the Society would not only endorse the action and services of the National Board, but give an emphatic expression of their views in regard to withholding congressional appropriations to carry forward this eminently benevolent work.

With reference to the action of the Society, at its last annual meeting, or its system of medical ethics, the President said :

"At the annual meeting in February, 1881, this Society appointed a committee of five, from among the most distinguished medical gentlemen of the State, to consider and revise the old code of medical ethics which had governed our action for nearly forty years. In conformity with the instructions given this committee, they presented their report at the annual meeting in 1882. . . .

"The report of the committee, as well as a substitute, was printed and placed in the hands of every member of the Society who desired a copy, that they might examine and vote deliberately and understandingly upon the changes reported for their consideration and adoption. After a general discussion, in which all present had an opportunity to express their views, the report of the committee was adopted by a large majority. The new code has not been received by the profession, or the medical press, in this and in other States, with cordiality or favor, but, on the contrary, by the most outspoken and emphatic opposition. . . .

"A year's consideration, a calm and dispassionate discussion of the matter, has greatly modified the views of the profession in reference to the objectionable measure, and I trust a more conservative sentiment exists to-day than at the time of its adoption."

Reference was then made to the action of the American Medical Association, at the annual meeting at St. Paul, in June, 1882, refusing admission to the delegates from the Medical Society of the State of New York, because they had taken the liberty to accept what was deemed a more progressive and liberal spirit in reference to established rational medicine, as it exists at the present time, and to adopt permission of consultation with any legally qualified practitioner of medicine, as not derogatory to the interest and dignity of the profession.

The advocates of the new code asserted that this is merely permissive, that no one is under obligation, expressed or implied, to meet an irregular practitioner in consultation, unless he prefers to do so; but in certain cases it would be illiberal, inhuman, and contrary to the spirit of the age, to withhold professional aid, because of "difference of opinion in creed or belief." The attention of the Society at this meeting was directed to a consideration of the merits of this subject, to confirm, modify, or abolish the new code, as in their wisdom and judgment they might deem most conducive to the welfare, dignity, and interests of the medical profession of the State of New York.

Death has entered our ranks during the past year and removed those who stood high in the esteem of our profession; Prof. James R. Wood, of the city of New York, Dr. George Burr, of Binghamton, and J. Foster Jenkins, of Yonkers.

The following Committees were then announced :

Business Committee.—Drs. Alex. Hutchins, of Kings; C. C. Gay, of Erie, and D. L. Hovey, of Monroe.

Committee on Credentials.—Drs. E. V. Stoddard, of Monroe; L. E. Felton, of St. Lawrence, and T. H. Squires, of Chemung.

A recess of ten minutes was then taken for purposes of registration.

COMMUNICATIONS FROM COUNTY SOCIETIES.

Communications were read from Westchester, Monroe and Broome Counties, declaring opposition to the new code.

It was moved that they be placed on file. Carried.

EXPERIMENTAL MEDICINE.

DR. J. G. CURTIS presented the report of the Committee on Experimental Medicine. It was stated that the bill presented by Mr. Henry Bergh to the Legislature was defeated.

Reference was made to the British Society for Scientific Research. The committee had placed themselves in correspondence with this body, and had obtained numerous valuable documents thereby.

The \$100 appropriated for the committee's expenses was not expended and was returned into the treasury.

The following resolution was offered :

Resolved, That this Society wish to declare anew its often-expressed conviction of the supreme importance to the Art of Medicine of scientific experiments upon living animals.

The report was adopted.

REPORT OF THE COMMITTEE ON BY-LAWS

DR. W. C. WEY, Chairman of the Committee, reported that they had examined the by-laws of the County of Warren, and recommended their amendments be adopted as in accordance with the by-laws of the State Society.

The report was accepted and the resolution adopted.

Dr. Wey also reported concerning a communication from Otsego County—with reference to dropping the names of permanent members from the roll for non-payment of dues, that it was not expedient to rescind or modify section 5 of article 6 of the by-laws of this Society.

The report was accepted and the recommendation of the committee adopted.

Dr. Wey also directed attention to the fact that only seven of the counties in the State had responded to the request of the Society made at its last annual meeting, to forward their by-laws for inspection as to whether or not they accorded with the by-laws of this Society, and offered a resolution requesting that, before the next annual meeting, the several counties be requested to submit their by-laws to this Society, for the purpose of ascertaining whether or not they are in accord with the by-laws of this Society; and that the Secretary be directed, by circular or otherwise, to call the attention of the County societies to the present and preceding resolutions.

The communication was received and the recommendation of the committee adopted.

The following gentlemen were made

MEMBERS BY INVITATION.

Drs. R. B. Granger, of New York; W. W. Potter, of Buffalo; A. H. Riley, of Clinton County; A. H. Moore, of Niagara County; C. E. Willard, of Catskill; T. A. Foster, of Maine; H. R. Starkweather, of Albany; H. C. Cooper, of New York; T. Z. Gibbs, of Fort Ann; E. Clark, of Sandy Hill; E. H. Squibb, of Brooklyn; M. J. Leroi, of Albany; T. W. Goff, of Cazenovia; R. C. McEwen, of Saratoga; H. S. Case, of Oneonta; G. D. Dunham, of Plattsburg; G. P. Clark, of Syracuse; D. F. Dayton, of Potsdam; Herman Bendell, of Albany; C. C. Bartholomew, of Ogdensburg; A. W. Phelps, of Chateaugay.

The report of the Business Committee referred to the resolution adopted at the meeting of 1882, limiting the duration of the reading of papers to twenty minutes.

DR. E. R. SQUIBB moved that the resolutions of last year be made to apply to this meeting, with the reservation that the Business Committee be allowed to extend the time in such cases as they deem proper. Carried.

REGARDING THE REPEAL OF ACTION OF LAST YEAR.

Dr. E. R. Squibb offered the following resolution :

Whereas, The Special Committee on the Code of Ethics, in its report at the last annual meeting, recommended a change in one part of the Code which was more in the nature of a revolution than of a revision, and therefore may be more radical than was expected or desired by the constituency of this society; and

Whereas, That report was adopted at a session where-

in only fifty-two members voted in the affirmative, and thus legislated for the entire profession of the State on a subject of vital importance in a direction which may not have been anticipated or desired by the profession at large; therefore,

Be it Resolved, That all the action taken at the annual meeting of 1881, in regard to changing the Code of Ethics, be repealed, leaving the Code to stand as it was before such action was taken.

Resolved, That a new Special Committee of five be nominated by the Nominating Committee of the Society, and be appointed by the Society to review the Code of Ethics, and to report at the annual meeting of 1884 any changes in the Code that may be deemed advisable.

Resolved, That the report of this Committee be discussed at the meeting of 1884, and be then laid over for final action at the meeting of 1885.

It was voted that it be the special order for an evening session, at 7.30 o'clock.

DR. H. S. PIFFARD then read a paper on

THE ETIOLOGY AND TREATMENT OF ACNE.

The author used the term acne in the restricted sense of inflammatory affections of the sebaceous glands, presenting a variety of grades.

Extensive quotations concerning the etiology of the disease were made from Wilson, Tilbury Fox, Duhring, and others, and finally his own belief was expressed that in the majority of instances acne is not a primary condition, but one which depends upon irritation and disease of other organs reflected upon the skin, especially those connected with the sexual and digestive systems. Four causes of acne had been recognised: 1, local irritation; 2, gastro-intestinal derangements; 3, masturbation; and 4, uterine derangements.

With regard to external causes, Dr. Piffard believed that they had little if anything to do with producing the disease. Gastro-intestinal disturbances exercised a marked influence in its production. From his own observation, he regarded it as exceedingly difficult to arrive at the truth concerning the actual effect produced in the etiology of acne by the third and fourth causes.

Papers by DR. W. W. POTTER, of Buffalo, on "Puerperal Eclampsia," and by DR. C. R. AGNEW, of New York, on "Notes on the Dangers of Specialists in Medicine," were read by title and referred to the Committee on Publication.

DR. SAMUEL SEXTON, of New York, then read a paper

ON REMOVAL OF FOREIGN BODIES FROM THE EAR.

The removal of foreign bodies from the ear was rarely necessary in adults.

The speaker stated that living insects and vermin were generally removed without trouble by the use of water.

The various articles found in the ears were briefly referred to. One was sometimes called upon to remove the small shells and sand that get into the ears of surf bathers. In these cases the special forceps which he had devised were very useful.

In removing foreign bodies it was important to be sure that there was a body present. It was best to have the child lie supinely on a low couch, the operator standing above. The speaker showed a specially devised forceps and also a curette. A very large number of instruments that had been devised for removing foreign bodies was shown.

DR. ROOSA, of New York, believed that none but a surgeon should attempt to remove a foreign body from the lower part of the auditory canal, or from the other side of the membrana tympani. But when seen, as they generally were seen at first by the general practitioner, in the auditory canal, where the bean, etc., has been placed by the child or some of its playmates, there was opportunity for the safe, easy treatment by the use of the syringe and warm water, and he believed that failure would scarcely ever occur if the case was in its inception. If

it was a case which had been manipulated, he preferred to use the hook or curette rather than the forceps, and of the hooks and curettes, that invented by Prof. Gross, or some of its modifications, answered the best purpose.

DR. KNAPP, of New York, agreed with nearly all that had been said by Dr. Sexton, and also by Dr. Roosa. From experiments and a good deal of experience in the use of forceps for removal of foreign bodies from the eye, he had been prejudiced against their use in the ear; but latterly he had used Dr. Sexton's forceps and found it to serve an excellent purpose—for managing such bodies as can be impressed, especially when located in the strait of the canal. Beyond that point foreign bodies could be removed only with very great difficulty.

Dr. Knapp exhibited a forceps with dividing branches, which seemed to be admirably adapted for this purpose. For removal of bodies which had been pushed beyond the strait, syringing would bring them to view, perhaps, and then hooks could be used for their extirpation. For subduing the inflammation and stopping the otorrhœa, he recommended alcohol and powdered boracic acid.

DR. E. GRUENING, of New York, thought too much stress had been laid upon the use of instruments, and he believed that by proper syringing the foreign body could always be dislodged.

DR. A. H. SMITH, of New York, directed attention to a suggestion by the late Dr. T. B. Smith, of Nyack—namely, to carry down to the foreign body a string laden with some adhesive substance which would dry readily and firmly attach it to the foreign body. A solution of gum shellac in alcohol was recommended.

THE PRESIDENT, DR. JEWETT, said that while it was almost always possible to remove foreign bodies with the syringe soon after they were impacted, later it was not possible. He related the case of a boy deaf in one ear for several months from an impacted bug. He removed this by etherizing the patient and using a bent silver probe.

DR. DAVID WEBSTER said that the most important thing was to be sure and see the object clearly first. Any one who did this would be very sure to act intelligently afterward.

DR. MATTHEWSON said that there was rarely need of great haste in these cases, and that proper deliberation should always be taken.

DR. SEXTON said that his paper was prepared on the assumption that the members knew how themselves to make a choice of the proper means for extracting foreign bodies. As regards removal of the auricle, he did not believe that that was a possible operation for the removal of small bodies, but was applicable for the removal of bullets from the bone parts adjacent.

Dr. Sexton thought that both instruments and sponging were dangerous in unskilful hands.

DR. W. B. CHASE, of Brooklyn, read a paper on

HOT WATER AS A HÆMOSTATIC.

The speaker thought that although this topic was old, it was a subject not yet fully understood or appreciated. The modus operandi of hot water as a hæmostatic was not yet thoroughly understood. Its special advantages are:

First.—That it exerts no dangerous influence upon the tissues and does not affect the rapidity of union.

Second.—Its effect is more prolonged than that of cold water.

Sponging the parts with hot water, during an operation, was thought not only to check capillary oozing, but to remove coagula and allow a better chance for union by first intention.

The water should be at a temperature of 115° to 125° or 130° F. The good effects in post-partum and in other uterine hemorrhages were illustrated by cases.

DR. C. R. AGNEW read his report as delegate to the American Medical Association. He stated that his credentials were refused, and that he was not admitted as a delegate. He received, however, many congratula-

tions from members upon the stand taken by the New York State Medical Society.

Some discussion upon the report arose, and it was voted that the matter be referred to the evening session.

The Society then adjourned to meet at 3 P.M.

TUESDAY—FIRST DAY—AFTERNOON SESSION.

The Society was called to order at 3 P.M. by the President.

MEMBERS BY INVITATION.

Drs. S. S. Cartwright, of Roxbury; W. W. Seymour, of Troy; H. Wiggins, of Elbridge; H. H. Dean, of Watertown; B. Burr, of New York; L. E. Holt, of New York; C. W. Green, of Albany; J. W. Whitbeck, of Rochester; J. E. Burdick, of Johnstown.

TREATMENT OF CHRONIC URTICARIA.

DR. J. H. FOX read a paper on the above subject, in which he spoke first of the disease as commonly due to functional disturbance of the abdominal viscera, combined with an abnormal condition of the sympathetic nervous system. To effect a cure we must always depend upon internal medication. An important class are those remedies which tend to eliminate from the blood imperfectly oxygenated material. Bicarbonate of soda, ζ ss., in carbonic acid water, half an hour before each meal. Colchicum is also a valuable agent, at the same time abstaining from meat.

Another important class of remedies are those which allay irritation of the gastro-intestinal tract, such as rhubarb, with occasional resort to mineral water. Bismuth, in some cases of gastric irritation, has proved exceedingly beneficial. Sulphurous acid, in drachm doses, three times a day in sweetened water, has proved especially efficacious.

A third class of remedies are those which act mainly upon the nervous system, such as quinia, arsenic, etc. Special reference was made to salicylic acid, balsam of copaiba, ergot, nettle-tea, etc.

The conclusion was that the treatment is largely empirical and highly unsatisfactory. The apparent value of drugs has been based partly upon careless observations, and partly upon the fact that the eruption often disappears suddenly without any treatment whatever.

The successful treatment must depend upon a knowledge of its etiology, and a diligent study of the causes of the disease will produce results more conducive to its cure than blind experimentation with remedies.

The paper was discussed by Dr. Rochester, of Buffalo, who spoke of an emetic of ipecac as especially serviceable in the treatment of acute urticaria, and also of some chronic cases of the affection.

REPORT OF COMMITTEE ON PRIZE ESSAYS.

DR. ROCHESTER reported that but one essay had been submitted, entitled "Pathological study of epithelioma of the lip." It was well written and showed much research, but the committee regretted that its author had debarred himself from receiving the prize because he had revealed his personal identity in the manuscript. A paper presented last year was rejected for the same reason, and strangely it was from the same writer.

Signed, T. F. ROCHESTER,
W. S. ELY,
W. W. POTTER.

The report was received and ordered to be entered upon the minutes.

Dr. Rochester also offered a resolution that prize essays subsequently submitted to the Society must be printed either by type-writer or other means. Adopted.

COMMITTEE ON THE PRESIDENT'S ADDRESS.

The President appointed as the special committee on the inaugural address, Drs. J. C. Hutchison, of Kings; T. D. Strong, of Chautauqua, and W. S. Ely, of Monroe.

COMMITTEE ON NOMINATIONS.

From the Society at Large:—Dr. S. O. Vander Poel, of New York. *From Senatorial Districts*: *First*—F. A. Castle, New York. *Second*—P. R. H. Sawyer, Westchester County. *Third*—Maurice Perkins, Schenectady. *Fourth*—Conant Sawyer, Essex County. *Fifth*—J. D. Spencer, Watertown. *Sixth*—George Douglas, Chenango County. *Seventh*—H. D. Didama, Syracuse. *Eighth*—F. F. Hoyer, Erie County.

DR. J. O. ROE, of Rochester, then read a paper entitled

THE PATHOLOGY AND RADICAL CURE OF HAY FEVER.

Hay fever was universally acknowledged to be a very obscure disease. This was thought to be due to the fact that investigators had not studied the character of the tissue of the nasal passages. The author's belief was that the disease was due to a peculiar susceptibility of this tissue. The three prominent theories heretofore held regarding hay fever are 1, the pollen theory, which is the oldest, and has been most widely received; 2, the vibrio theory, suggested by Helmholtz in 1868; 3, the neurotic theory, propounded by the late Dr. Beard.

The writer discussed these theories, and contended that they were insufficient to explain all the phenomena of the disease. He then took up the subject of the sympathetic relations between different parts, by which irritations in one region cause disturbances in another.

In the nasal passages, along the turbinated bones, there is a large amount of very vascular or erectile tissue, which has been called the corpora cavernosa of the turbinated bones. This tissue is under the control of the vaso-motor system, and is very easily affected by irritants. In hay-fever patients the tissue is very susceptible to certain irritants, like pollen, dust, etc.

The reader reported five cases of hay-fever patients from whom this tissue had been removed. The patients were all cured. Another physician had treated three cases in the same way with like results.

Dr. Roe's

CONCLUSIONS

were:

First.—Hay fever is an affection not confined to any age or sex, and is not caused by the pollen of flowers or grasses, or by dust or irritating substances alone.

Second.—In some persons the nasal mucous membrane is very susceptible to certain floating irritants, while in others it is not.

Third.—This peculiar hyperæsthesia is caused by a diseased condition of the erectile tissue in the nasal passage.

Fourth.—The systemic effects in hay fever, viz., the lung, laryngeal, and other troubles, are all reflex in character, and are due to the local disturbance in the nose.

Fifth.—Treatment during an attack can only be palliative. The patient had best go where the floating irritating particles do not exist.

Sixth.—Curative measures should be attempted during the intervals of the attack. These curative measures consist in the entire removal of the diseased tissue.

The paper was discussed by Drs. Wey, of Elmira (who took exceptions to Dr. Roe's views); Sabin, of West Troy; Prout, of Brooklyn; Greene, of Homer, and Pomeroy, of New York.

OBITUARY NOTICE.

An obituary notice of Dr. Devillo White, of Sherburne, was presented by Dr. George Douglas, of Oxford, which was referred to the Committee on Publication.

DR. W. F. MITTENDORF, of New York, then read a paper

ON A NEW METHOD OF APPLYING REMEDIES TO THE EYE.

The method consisted in the use of impalpable powders, made of gum arabic, with a very small quantity of sugar of milk, and containing the alkaloid to be used.

The advantages claimed were that the preparations kept for an indefinite time unimpaired, and the quantity put into the eye could be regulated precisely. The disadvantages attending the use of aqueous solutions, such as formative fungi, which changed the strength of the solution; of vaseline, which in many instances simply suspended, and did not dissolve the agent used, etc. The powder is to be applied after the ordinary manner of applying calomel, from a camel's hair-brush.

DR. MITTENDORF also exhibited a new

EYE SPECULUM

involving the same principle used by Dr. Jarvis in his nasal speculum, namely, the sliding ring.

The communications were discussed by Drs. Pooley, of New York; Roosa, of New York; Squibb, of Brooklyn, and Gruening, of New York.

MEMBERS BY INVITATION.

The Committee of Arrangements announced the following: Drs. Wm. Hailes, of Albany; G. S. Munson, of Albany; John Edwards, of Gloversville; D. H. Cook, of Albany; J. B. Stonehouse, H. Lilienthal, J. C. B. Graveline, G. L. Ullman and S. E. Ullman, of Albany; S. G. De Le Matyr, of Duaneburg; C. B. Herrick, of Troy; R. H. Sabin and W. B. Sabin, of West Troy; E. B. Tefft, S. O. Vander Poel, Jr., and Frank Townsend, of Albany.

DELEGATES FROM OTHER STATE MEDICAL SOCIETIES.

Drs. Wm. Ingals and H. W. Williams, of Boston, delegates from the Massachusetts State Medical Society; E. F. Upham, of Vermont State Medical Society, were introduced to the Society and responded in appropriate words.

Two communications received from Clark Bell, Esq., New York, were referred to the Committee on Legislation, to be reported upon at the next meeting.

DR. DAVID WEBSTER then read a paper on

SYPHILITIC DISEASE OF THE LABYRINTH.

Two cases illustrating this trouble were related. They were characterized by deafness, tinnitus, and occasionally vertigo. In one case only one ear was affected. One case was cured; the other decidedly relieved.

DR. ORIN D. POMEROY read a paper entitled

SYPHILITIC DISEASE OF THE MIDDLE EAR, LABYRINTH, AND ACOUSTIC NERVE.

The writer discussed the subject of the inflammation of these parts together, because their differentiation clinically was not often possible. The symptoms were enumerated, and consisted of deafness, vertigo, tinnitus, often facial paralysis, etc. Various accompanying troubles were mentioned. As to the pathology, it was thought that the middle ear was oftenest involved. The points in diagnosis and treatment were given.

Dr. Pomeroy's paper gave rise to discussion, participated in by Drs. Roosa, Howe, of Utica, and Sexton, of New York.

DR. GRUENING then read a paper

ON THE INFUSION OF LICORICE BEAN (ABRUS PRECATORIUS) IN THE TREATMENT OF INVETERATE PANNUUS.

The treatment of pannus by inoculation was discussed, and the very serious obstacles to its use. Recently, De Wecker, of Paris, had experimented with licorice, and had found it to secure all the good results of inoculation without any dangers.

Dr. Gruening tried this method, but at first with no result, owing to the beans not being fresh. He then obtained a new supply, and used the infusion upon two cases of inveterate pannus, which had been before treated by various methods. The results were so brilliantly successful that the patients could be discharged cured in ten days.

The formula for making the infusion was as follows: Take 36 beans, pulverized, place in 500 grammes cold

water for twenty-four hours, then add 500 grammes of hot water, and filter immediately after cooling. Brush it three times a day upon the surface of the lids. It produces in a few days a decided croupous or purulent inflammation.

DR. LOUIS ELSBERG read a paper entitled

A NEW TONGUE SPATULA AND THE PROPER METHOD OF USING IT.

He referred to a paper presented to the Society just nineteen years ago. At that time he stated that the ordinary tongue spatulae were not much better than a spoon-handle. The various points required for a perfect spatula were enumerated, and some of the changes which he had found necessary to perfect the spatula then presented.

DR. DAVID LITTLE, of Rochester, read a paper entitled

A SINGLE CASE OF OVARIOTOMY.

The case was a successful one, although no Listerism was used. The speaker thought that scrupulous cleanliness was sufficient without antiseptics.

Dr. Gruening's paper was discussed by Dr. Pomeroy, of New York, after which the Society adjourned to meet at 7.30 P.M.

TUESDAY—FIRST DAY—EVENING SESSION.

SUSTAINING THE NEW YORK CODE.

The Society being called to order, the resolution for the special order of the evening was read. The Society went into Committee of the Whole, DR. HUTCHINS, of Brooklyn, taking the chair.

DR. E. R. SQUIBB presented his resolution and read an argument to prove that the present Code of Ethics was illegally adopted, because it was not presented to the County Societies first.

A prolonged debate followed. Drs. Roosa, Piffard, Hopkins, Seymour, Didama, Rochester, Gouley, Agnew, and others taking part.

The Committee of the Whole then rose and reported progress to the Society. The Society in Session then voted upon Dr. Squibb's resolutions, which failed to pass by a vote of 99 to 105, the yeas and nays being called.

DR. ROOSA then presented the declaratory resolution which he had presented at the meeting of 1882. It was voted to postpone its consideration for twelve months.

DR. J. G. ADAMS read a protest against the action of the Society regarding the Code of Ethics.

WEDNESDAY, FEBRUARY 7TH—SECOND DAY—MORNING SESSION.

The Society was called to order at 10 A.M. by the President.

Prayer was offered by Rev. Dr. McGee.

MEMBERS BY INVITATION.

W. R. Pierson, of Schenectady; T. A. Foster, of Portland, Me.; H. M. Eddy, of Geneva; G. H. Newcomb, C. L. Merrill, and W. H. Munson, of Albany; I. G. Johnson, of Greenfield; A. B. Husted, of Albany; H. M. Eddy, of Ontario County; J. C. Carson, of Willard; I. de Zouche, of Gloversville; D. G. Tucker, of Albany; D. M. Wilcox, of Lee, Mass., and Thomas Riley, of Adams, Mass.

DR. F. E. BECKWITH, of New Haven, was introduced as delegate from the Connecticut Medical Society.

TREASURER'S REPORT.

DR. CHARLES H. PORTER, of Albany, Treasurer, read his report, which showed a balance in the treasury of \$1,264.21. It was referred to an Auditing Committee consisting of Drs. M. Perkins, W. S. Ely, and Hopkins, of Buffalo, which subsequently reported that the accounts of the treasurer had been found correct. The report of the Committee was adopted.

Report on the Merritt H. Carl fund showed \$149.26 available for purposes of prize essays.

DR. F. R. STURGIS reported for the

COMMITTEE ON LEGISLATION.

Several points were involved in the report, and a resolution was offered asking for an appropriation of \$500. to be used by the Committee on Legislation in defraying necessary expenses incident to looking after medical legislation and the interests of the medical profession in the passage and obstructing the passage of medical laws.

With regard to the two bills forwarded by Mr. Clark Bell, the Committee recommended that they lie over and be transferred to the next Committee on Legislation.

DR. VAN DE WARKER offered certain amendments, which he subsequently withdrew.

A communication from the Chancellor of the University of the State of New York concerning

BOARDS OF EXAMINERS, FOR THE EXAMINATION OF CANDIDATES FOR LICENSES TO PRACTISE PHYSIC AND SURGERY,

was read by Dr. Hutchins, on behalf of Dr. Vander Poel, in which the desire was expressed to have the co-operation of the State Medical Society in the appointment of persons to fill vacancies now existing in the present Board.

DR. HUTCHINS moved that a Committee of three be appointed to confer with the Regents of the University in the matter referred to. Drs. S. O. Vander Poel, E. M. Moore, and A. Jacobi, were appointed as the Committee.

REPORT ON THE PRESIDENT'S INAUGURAL ADDRESS.

DR. J. C. HUTCHISON, Chairman, reported that, in the opinion of the Committee, further legislative enactment is unnecessary; that the study of medicine by those deficient in preliminary education should be discouraged; that those medical schools should be recommended which furnish the most thorough course of instruction; that a State Board of Examiners cannot be made so free from political influence as to entitle it to recommendation; that State Boards of Health should be supported; that there should at present be no change with regard to the place where the annual address is delivered; but that it *would* be well hereafter not to require an annual address, as all matters pertaining to the Society and the profession could be incorporated in the inaugural address.

The report was accepted and placed on file.

DR. A. JACOBI made a report of the Committee on the President's Address in 1882. The report concerned the establishment of

HOSPITALS FOR SCARLET FEVER.

The history of the successful attempt to provide for such a hospital in New York City was given.

The report was accepted.

DR. W. S. ELY reported as

CENSOR TO THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF SYRACUSE.

The report was favorable to the qualifications of the candidates for examination.

DR. MUNDÉ then read a paper on

NON-PUERPERAL UTERINE HEMORRHAGE.

The paper is published in full in the present number.

It was discussed by DR. VAN DE WARKER, of Syracuse, who regarded it as a most valuable and practical communication. It was also discussed by DR. B. F. SHERMAN, of Ogdensburg.

DR. F. A. CASTLE, of New York, reported a resolution to the effect that a complete list of

REGISTERED PRACTITIONERS

in the State be made and appended to the volume of Society Transactions. After considerable discussion the

resolution was laid on the table, on the ground that such a work belonged more properly to the State.

DR. DIDAMA, of Syracuse, presented the following resolution as an

AMENDMENT TO THE BY-LAWS.

"That all action taken at the annual meeting of 1882 in regard to changing the Code of Ethics, be repealed, leaving the code to stand as it was before such action was taken."

It was received and recorded to be acted upon at the meeting of 1884.

Laid over under the rule.

An obituary of S. M. Van Alstyn, of Richmondville, prepared by Dr. A. Vandever, of Albany, was read by title and referred to the Committee on Publication.

DR. LOUIS ELSBERG read a paper on a

FORCEPS ECRASEUR FOR REMOVING NASAL POLYPI.

A number of instruments were shown, and the special advantages of the speaker's were described.

It simply replaced the transfixing needle, as in Jarvis's snare, with a forceps.

DR. ROE showed a long serrated clamp which he had used to seize the tissue, crush it, and then cut it off.

DR. H. KNAPP, of New York, read a report on the eighth series of

ONE HUNDRED CATARACT OPERATIONS.

The results were that among one hundred cases there were ninety good results, seven moderate results, two failures, and one case not recorded, as the patient died of hæmaturia. The method of operating was Graefe's modified linear. The speaker thought that he could obtain no better results, as there must always be a certain number of failures, owing to the unruliness of patients and other causes. Dr. Knapp said that in cataract operations there must be more than antisepsis—there must be effort to secure primary union. To secure this there must be absolute cleanliness in every detail and perfectly smooth incisions. The speaker had used strict antisepsis (Listerism) in every other case, but got no better results than when these measures were not employed. He made a clean incision into the capsule instead of tearing it. After the contents were removed, healing by primary union took place. The capsule was then removed two weeks later in many cases, by operation with a scalpel needle.

The Society then adjourned to meet at 3 P.M.

WEDNESDAY—SECOND DAY—AFTERNOON SESSION.

The Society was called to order at 3 P.M. by the Chairman of the Business Committee, and DR. W. C. WEY, of Elmira, was elected President *pro tem*.

DR. ROOSA, of New York, then read a paper on

THE INJUDICIOUS USE OF THE SULPHATE OF QUININE.

It appears in the present number of THE RECORD. It was discussed by DR. T. R. POOLEY, of New York, who cited cases confirmatory of Dr. Roosa's statements; by DR. JACOBI, who thought sufficient distinction had not been made between pyæmia and septicæmia; in pyæmia it had been established that quinine counteracted the migration of white blood-corpuscles, and so was beneficial in pyæmia; while in septicæmia but slight benefit follows its administration.

DR. W. MANLIUS SMITH spoke of some observations made with reference to the different effects produced upon himself by cinchonine, cinchonidia, and quinia; as that cinchonine affected his vision more than did quinine, and it also diminished the urinary secretion, etc.

DR. ROOSA did not believe there was any such distinction between pyæmia and septicæmia as had been made by many authorities.

The paper was also discussed by DR. INGALLS, of Boston.

DR. H. W. WILLIAMS, of Boston, then made some remarks on

ERYSIPELAS EXTENDING INTO THE ORBIT.

He had seen four cases of orbital cellulitis resulting from facial erysipelas, and had never met with a case of this kind until two years ago, nor had any been brought to his notice in literature until after he had seen his first case. The symptoms were pain, projection of the eyeball directly forward rather than to one side, pale condition of the fundus, sensation of fulness, great engorgement of the tissues, swollen lids, chemosis of the eyeball. The treatment recommended was early evacuation of the pus, and this he did in all his cases by means of deep punctures.

In the discussion of Dr. Williams's paper, DR. T. R. POOLEY, of New York, referred to a marked case of acute protrusion of the eyeball, which he had treated by incision, and with success. He thought that a single large incision was the preferable method of treatment. He thought the loss of sight which sometimes occurred was due to pressure on the optic nerve. The disease had been described by Von Graefe under the name of retrobulbar neuritis.

DR. DANIEL LEWIS, of New York, presented a paper on "The Development of Cancer from Non-Malignant Disease," which was read by title.

DR. ROBERT NEWMAN read a paper entitled,
THE USE OF SUPPOSITORIES OF GELATINE FOR LOCAL MEDICATION.

The speaker had used cocoa butter and various other substances, but with no good result. Two years ago, he began to use bougies of gelatine and with great success. The speaker showed suppositories of this material for the urethra, rectum, nose, vagina, sinuses, etc.

Especial attention was called to the urethral bougies. Their advantages lay in being neat in appearance, soft, elastic, flexible, not easily broken, and slowly dissolved. They contained the medicines equally dissolved and distributed. They are not injured by time or temperature.

The best time to introduce them was at night and not in the daytime. They had better be moistened with water. In order to keep them in, apply a small piece of cotton at the urethral orifice, and over the latter a bit of adhesive plaster. They are to be used *only* when the urethra is acutely inflamed and will not tolerate anything.

A number of cases were reported. In prostatitis great care must be used; ten to twelve bougies will generally be sufficient.

DR. POOLEY, of New York, read a paper on
RUPTURE OF THE CHOROID.

A number of cases were related illustrating this trouble. The patient's history, with distorted or more or less loss of vision and the ophthalmoscopic appearances of a crescentic white patch with concavity toward the optic disk, revealed the disease.

DR. WILLIAMS, of Boston, and DR. POOLEY discussed the paper.

DR. FREDERICK HYDE, of Cortland, read a paper entitled,

WHEN SHALL THE TREPHINE BE USED IN FRACTURE OF THE SKULL?

The general tenor of the paper was in favor of a non-conservative treatment of cranial fractures. The writer especially urged the use of the trephine in cases of fracture, even when symptoms of pressure were not present.

DR. T. H. SQUIRE, of Elmira, read a paper on

SOME POINTS IN RESPECT TO OVIOTOMY.

The first was with regard to the proper form of trocar. The speaker thought that a plain tube with a slot half an inch from the extremity would be an improvement on that generally used. The inner canula might often be dispensed with.

The second point was as to the time when ovariectomy

should be performed. There used to be a belief that the operation should be delayed. The speaker thought that the tendency now was to perform it as early as possible. A course of preparatory treatment would always be needed.

Dr. Squire also gave the history of a case of

VESICAL CALCULUS

occurring in a girl seventeen years of age. It was removed through the urethra, which had been fully dilated. The nucleus of the stone was some foreign body, like a pin or needle, which had been left in the bladder.

The Committee of Arrangements announced the following as

MEMBERS BY INVITATION:

Drs. Lewis Granger, of Tioga County, Pa.; L. A. Tourtellot, of Utica; A. James Browne, of Newport; and C. W. Hamlin, of Middleville; J. D. Lomax, of Rensselaer County; G. E. Lyon, of West Troy; W. C. Cooper, of Troy; Wm. Stevens, of New York; and D. H. Cooks, of Albany.

DR. L. E. FELTON, of Potsdam, then read a paper on the use of

LACTIC ACID IN DIABETES.

Eight cases were reported in which favorable results had been obtained with this drug. The patients presented the ordinary symptoms of those suffering from glycosuria, passed large quantities of urine with high specific gravity, and containing sugar. Lactic acid was given, a drachm and a half daily, diluted in a quart of water, and an exclusively meat diet was adopted. Meat, sour milk, and lactic acid constituted the chief factors in the treatment, the drug being given in smaller quantities than recommended by Cantanni.

DR. WEY, of Elmira, referred to a case in which the patient had lost thirty, or more, pounds in weight, and was passing six gallons of saccharine urine daily. The ergot treatment recommended by Dr. DaCosta was adopted, and in a very short time the daily quantity of urine was reduced eighty ounces, the skin became moist, the specific gravity of the urine fell, the sugar materially changed in quantity, and there seemed to be fair prospect of recovery.

DR. FRENCH, of Montgomery County, thought that strict attention to diet could do more in these cases than could medicine.

DR. JACOB regarded restriction of the diet as the principal factor in the treatment of diabetes, as a rule. At the same time it was well known that the treatment of diabetes nowadays is much more successful than it was thirty years ago, when it was supposed that every case of the disease would invariably terminate fatally. He then referred to the fact that sugar occurs in the urine temporarily not very infrequently; and also mentioned three cases in which sugar had promptly disappeared from the urine under the internal use of eight grains of iodoform daily, together with restricted diet. He believed that if the urine was tested for sugar as frequently as it is for albumen, that sugar would be found to be present in a much larger proportion of cases than is generally supposed.

DR. W. GILLIS, of Fort Covington, then read a paper entitled,

REPORT OF A CASE OF PUNCTURED WOUND OF THE SKULL THROUGH THE ORBIT WITH COMPLETE AMNESIC APHASIA.

The patient, a boy, was struck in the eye with the prong of a dung-fork, which penetrated the skull through the orbit for a distance of three or four inches. The child was unconscious, and remained so for three days. Facial paralysis and hemiplegia of the right side appeared and lasted for about three days, gradually disappearing. Eight months later the child was entirely recovered, except that from the beginning it had been unable to articulate. Hearing, vision, and all the special senses were perfect. Intelligence was unimpaired.

The paper was discussed by Drs. W. S. Ely, of Rochester, H. R. Hopkins, of Buffalo, B. F. Sherman, of Ogdensburg, and F. Hyde, of Cortland.

The Society then adjourned to meet in the Assembly Chamber at the new Capitol, at 8 P.M., to listen to the President's annual address.

WEDNESDAY—SECOND DAY—EVENING SESSION.

ANNUAL ADDRESS OF THE PRESIDENT—SOME OF THE PERILS TO LIFE FROM THE PREVENTABLE DISEASES.

"Life and health may be regarded as the sum of all good to the human race." The health, happiness, and prosperity of mankind must be intimately and inseparably connected with and dependent upon its sanitary condition. The people are slow to comprehend the dangers that arise from trivial causes, and from habits of life in which they have indulged for years, because they are unable to trace any direct connection between obscure and indirect causes and positive results. They are also unwilling to accept the fact that disease and death may result from their own carelessness and uncleanly practices.

The excessive civilization of modern times, the æstheticism of the age has blinded our eyes and perverted our judgments, and led us to stray from the habits of primitive times that gave our ancestors more vigorous constitutions and more stalwart frames than we of this generation can boast.

There are some conditions which greatly affect the health of the community over which sanitary work has little or no control; as, for example, the temperature and moisture of the air, variations in which greatly influence the health of the people. But these are not the agents with which we are to deal in endeavoring to check the progress of diseases, so much as it is certain combinations of heat, moisture, and animal or vegetable decomposition, occurring either in the course of nature or, more often, as the sequence of man's careless and slovenly habits. To these we are to look for predisposing conditions, even though we may not always see the actual cause of disease. Attention was then directed to preventive medicine and to the work of the general practitioner in relation to it. National boards of health must be backed by local boards, and local boards must be sustained by individual practising physicians.

At this point special attention was directed to the inability of the majority of practising physicians to properly advise their patients and patrons in sanitary matters, owing to their deficiency in knowledge of the first principles of sanitary science, which involve a study of defects in drainage, the best means of furnishing and protecting water supply, securing ventilation, etc. A knowledge of chemistry, natural philosophy, and the natural sciences generally, should be had, and here the President passed to a consideration of the demand for more thoroughly educated men before entering upon the study of medicine. The advantages to be derived from the observation of contagious and epidemic disease in rural districts, where it is isolated as it were from special prejudicial influences, were then presented. Brief reference was then made to the part which germs are supposed to play in the production of disease, and a conservative conclusion was reached.

Attention was then directed to the influence of defective drainage and sewerage upon the health of the people, and the President believed it to be safe to give patients the benefit of the doubt whether it be established or not that diphtheria, scarlet fever, or other diseases are produced by sewer-gas or micro-organisms. The influence of wet soil, cesspools, ground water in building sites, and of contaminated water, was then referred to. The profession needs gentlemen in every district, who, in general information and culture, shall be leaders among the people in every good enterprise, and give the dignity to and respect for the profession of medicine which it does not fully possess to-day. Under the present system of medical education, the President failed to see the pros-

pect for the achievement of this desirable result. When such a result shall have been obtained, and when preventive medicine shall have attained its destined eminence we shall hold a prouder position and be more than ever the benefactors of the race.

THURSDAY, FEBRUARY 8TH—THIRD DAY—MORNING SESSION.

The Society was called to order at 9 A.M. by the President. Prayer was offered by REV. DR. REESE.

DR. SMITH, from the Committee on Publication, reported that the delay caused in issuing the last volume of the "Transactions" was due to failure on the part of authors to return proof-sheets.

DR. HOWE, of Buffalo, introduced the following as an amendment to the By-laws: "That the Code of Ethics of the American Medical Association be substituted for the one adopted by this Society in 1882, and having thus gained the unquestioned right to representation that our delegates be instructed to advocate such modification of that Code as shall be in accordance with a spirit of greater liberality, or if advisable to urge its entire abolition."

DR. PORTER, of Albany, offered a resolution that a committee be appointed to confer with the Capitol commissioners concerning appropriating a room in the new building for the use of the State Medical Society. Adopted, and Drs. Porter, Bailey, and Mosher, of Albany, were appointed.

Dr. Porter also offered a resolution that a committee be appointed to consider the propriety of publishing, and to publish, if deemed desirable, the "Transactions," from 1837. Adopted, and Drs. W. M. Smith, C. H. Porter, and F. S. Curtis were appointed.

OFFICERS FOR ENSUING YEAR.

The Committee on Nominations submitted the following report, which was adopted:

For President—Alexander Hutchins, of Brooklyn.

For Vice-President—H. G. P. Spencer, of Watertown.

For Secretary—William Manlius Smith, of Syracuse.

For Treasurer—Charles H. Porter, of Albany.

For Censors—Southern District: J. W. S. Gouley, Austin Flint, F. A. Castle, of New York. Eastern District: C. E. Nichols, M. H. Burton, W. S. Cooper, of Troy. Middle District: Alonzo Churchill, S. G. Walcott, J. K. Chamberlayne, of Utica. Western District: C. C. Wyckoff, Thomas F. Rochester, F. F. Hoyer, of Buffalo.

Committee of Arrangements—S. B. Ward, J. S. Mosher, of Albany; W. S. Ely, of Rochester.

Committee on By-Laws—W. C. Wey, of Elmira; H. G. Piffard, of New York; Wm. Manlius Smith, of Syracuse.

Committee on Hygiene—E. V. Stoddard, of Rochester; Stephen Smith, of New York; Jacob S. Mosher, of Albany; P. R. H. Sawyer, of Bedford; Caleb Groen, of Homer; Edwin Hutchinson, of Utica; Theodore Dimon, of Auburn.

Committee on Legislation—Jacob S. Mosher, Albert Vanderveer, of Albany; F. R. Sturgis, of New York.

Committee on Medical Ethics—C. R. Agnew, of New York; E. M. Moore, of Rochester; S. O. Vander Poel, of New York.

Committee on Prize Essays—Thomas F. Rochester, of Buffalo; Wm. S. Ely, of Rochester; W. W. Porter of Buffalo.

Committee on Publication—Wm. Manlius Smith, of Syracuse; Charles H. Porter, of Albany; George J. Fisher, of Sing Sing.

Curator for the College of Medicine, Syracuse University—C. S. Starr, of Rochester.

For Permanent Members—First District: F. P. Foster, Laurence Johnson, Alfred C. Post, David Webster, of New York; John Byrne, of Brooklyn. Second Dis-

tract: J. J. Linsen, of Tarrytown; E. F. Quinlan, of Monticello. Third District: S. B. Ward, of Albany; C. E. Willard, of Catskill. Fourth District: A. J. Browne, of Herkimer; A. M. Phelps, of Chateaugay. Fifth District: J. N. Goff, of Cazenovia; J. D. Spencer, of Watertown. Sixth District: L. D. Witherill, of Union; D. W. Birge, of Peach Orchard. Seventh District: J. B. Chapin, of Willard; Alfred Mercer, of Syracuse. Eighth District: W. W. Potter, of Buffalo; J. W. Whitbeck, of Rochester.

For Honorary Members.—T. J. Turner, of the United States Navy and National Board of Health; William Goodell, of Philadelphia; Lockhart Robinson, of Edinburgh, Scotland.

Eligible to Honorary Membership.—W. B. Robinson, of Edinburgh, Scotland; W. Bronson, of New Canaan, Conn.; Professor J. Cabell, of the University of Virginia; Professor J. G. Richardson, of the University of Pennsylvania; Professor J. T. Whitaker, of Cincinnati, Ohio; W. Hingston, of Montreal, Canada.

Delegates to State Medical Societies.—Massachusetts: Geo. C. Smith, of Rondout; E. N. Brush, of Utica; P. V. S. Pruyn, of Kinderhook; George G. Hopkins, of Brooklyn. New Hampshire: Wm. M. Chamberlain, of New York. New Jersey: J. C. Hutchison, of Brooklyn; Robert Newman, of New York. Ohio: Thomas R. Pooley, of New York. Pennsylvania: H. C. May, of Corning; Sol. Van Etten, of Port Jervis; T. D. Strong, of Westfield. Vermont: D. Lyon, of Plattsburg; A. G. Long, of Whitehall; C. C. F. Gay, of Buffalo. Connecticut: P. R. H. Sawyer, of Bedford; E. V. Stoddard, of Rochester; George Douglass, of Oxford.

Delegates to the Canadian Medical Association.—B. F. Sherman, of Ogdensburg; H. G. P. Spencer, of Watertown; L. E. Felton, of Potsdam; J. C. Hutchison, of Brooklyn; R. J. Robb, of Amsterdam.

Censor for the College of Medicine, Syracuse University.—C. S. Starr, of Rochester.

Respecting the American Medical Association, the Committee reported that it deemed it inexpedient at present to name any delegate to that body.

A vote of thanks was extended to the President for the impartial manner in which he presided, and the Business Committee recommended that the Society adjourn to meet on the first Tuesday in February, 1884.

MASSACHUSETTS HEALTH STATISTICS.—The annual report of the Massachusetts Board of Health, Charity, and Lunacy, for 1881-2, has recently been submitted to the Legislature.

Under the head of public health, it is stated that Massachusetts is more exposed to small-pox than any other State, and in 1881-2 it appeared in about thirty cities, but no extensive mischief resulted. The deaths from this disease in the State in 1882 were less than the small-pox deaths in Chicago in one week. The presence here of small-pox is due to immigration at our ports, paper, rags, and the Canadian immigration by land. The year 1882 was one of average health, and no disease can be said to have prevailed excessively.

Malarial fever has not appeared in so many towns east of the Connecticut as in the previous years, but in the western part of the State it seems to have been more prevalent than ever. In connection with the National Board of Health and the State Boards of New York, Connecticut, and Rhode Island, this board took steps for a combined investigation of the subject of malarial fever. A mass of valuable information has been secured, but the laboratory work, by reason of the failure of the National Board to obtain the usual appropriation, was suspended in July.

The aggregate number of the insane in the State is at least 5,100, a net increase of about 200. The latest investigations prove that not more than 50, probably not more than 30 per cent. of the insane permanently recover. Only about two-fifths of the insane are Americans.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, February 10, 1883.

THE MEETING OF THE STATE SOCIETY.

THE meeting of the Medical Society of the State of New York was, as will be seen by our full report, one of notable interest. The attendance was unusually large, every county society being duly represented. There was one feature in connection with the papers presented which calls for special comment. The lack of variety of the subjects discussed by them was strikingly apparent.

If a stranger had dropped in at any time during the sessions he could very justly conclude that the Medical Society of the State of New York was specially interested in one of two things—either the study of diseases of the eye and ear, or the merits of the question of freedom in consultations. There was altogether too much of both of these subjects to develop a proper scientific interest on the part of the general practitioner in the proceedings. It was perfectly proper to make the discussion of the merits of the new Code a special order of business for one evening, but that was enough. As to quantity of material, so might it be said of papers by our good friends who have taught us so much concerning diseases of the eye and ear.

Although each of these papers had been carefully prepared, and presented the latest views on their subjects, they in the main lacked practical application to the wants of the general practitioner. While there was an embarrassment of riches in one direction there was a notable falling off in another. This should hardly be the case in a society composed, as this is, largely of men who, in the broadest sense of the term, are general practitioners, and whose real interest consists in the freest opportunities for exchanging news and comparing experiences in the treatment and diagnosis of the commoner diseases. Perhaps the fault is as much to be laid at the door of the average member, who is disinclined as a rule to read papers, as to the specialist, who is more of a worker in that direction and who occupies time which otherwise might be entirely unappropriated to scientific purposes. Hence the complaint that the specialists are generally to the front should react upon the very members who have it in their power to divide the honors by contributing their own proportion of work. The example of New York in respect to scientific zeal should be imitated by the rural brethren, whose fields of observation are large enough to afford them every opportunity for the contribution of most valuable experience, and who really have

no excuse for not adding to the scientific interest of the meeting accordingly.

A great deal of the interest of the meeting centred, as might have been anticipated, upon the discussion of the new Code. This discussion took place before the largest meeting the society ever held. The freest interchange of opinion was invited and the conclusions arrived at were deliberate and pronounced. It is a matter for congratulation, that, with few exceptions, a becomingly charitable spirit characterized the debate and that all the arguments pro and con that were collected from so many sources during the past year were quite exhaustively presented.

The vote against Dr. Squibb's resolutions to restore the American Code, was unexpectedly large, considering the amount of extra-State and extra-professional pressure that had been brought to bear upon County Societies. The matter can now be safely left where it is.

We may be permitted to say, however, in the greatest courtesy, that the present action of the Society conclusively shows that New York State is determined to take care of its own ethical affairs and resents meddling interference from outside influences.

As a result of the meeting, we believe it to be settled beyond all cavil and question that the majority of the physicians in the State are in favor of the non-restrictive Code. Equally strenuous efforts were made by both parties to have all their forces represented at the recent meeting. The vote was fairly taken, and plainly showed the sentiments of the delegates and members. We need hear no more now about the arts of "New York specialists," since, out of the 105 votes, hardly a dozen were cast by these gentlemen.

As a further confirmation of the fact that the vote expressed the sentiment of New York State, we would state that Dr. Manlius Smith, the secretary of the Society, received nearly seven hundred answers to queries from practitioners throughout the State to his card, asking their opinion of the Code. Of these, a very considerable majority favored the present Code. Yet a large part of the answers came from the country, while it has been claimed that the cities represent the real strength of non-restrictive principles.

ABDOMINAL SECTION.

DR. J. EWING MEARS, of Philadelphia, presented to the College of Physicians of Philadelphia a *resumé* of twenty-five cases of abdominal section, in which some interesting and instructive facts are considered. Twenty-two of these operations were performed for the removal of tumors of the ovary. In none of the twelve cases in which aspiration or tapping was performed did any serious results occur, nor were there evidences in the operations which followed of complications due to the previous aspiration or tapping. The incisions were closed by metallic sutures, the needle being carried so as to include the peritoneum. In all cases but one the pedicle was secured by the application of the clamp; in the case excepted a carbolyzed catgut ligature was applied and the pedicle was returned to the abdominal cavity. In one instance of an extremely short pedicle, where, in fact, the wall of the cyst was separated not more than half an inch from the uterus, a double animal

ligature was applied, which failed to control the hemorrhage. The clamp was then applied over the ligature, bringing the uterus well up between the edges of the incision. Although the patient had a tedious convalescence, the ligature and clamp came away in good time and the abdominal incision healed kindly. Beneath the cicatrix the uterus could be distinctly outlined, and after the return of the patient to her usual duties no complaint was made of pain caused by traction upon the organ. In one case only was there noticed a slight tendency to the occurrence of ventral hernia. The healing of the abdominal incision was not materially delayed by the application of the clamp. In three cases menstruation took place by the pedicle, but did not produce any serious inconvenience. In one of the three fatal cases which occurred, the ligature was applied and the pedicle returned to the abdominal cavity; death resulted on the third day from septicæmia. In this case the cyst was adherent in every part to the parietes and viscera. In fourteen cases the antiseptic methods were employed, the spray, however, being omitted. One of these cases proved fatal. The constitutional effect of the carbolic acid has been observed in two or three cases in the condition of the urine, other than this no symptoms were noted. Thirty to sixty grains of quinine, in divided doses, were given in the twenty-four hours preceding the operation, with a view to obviate shock, and in this respect its use has been attended with success.

THE CIVILIZED AND UNCIVILIZED WOMAN IN LABOR.

THE remark of Carlyle that science originated from a belief of man "that there was something wrong" has certainly received confirmation in the literature of the science of obstetrics.

The blessings of civilization with its attending comforts and advantages, so much coveted by mankind, has its reverse side of horrors, the worst aspect of which is seen in the present physical condition of women.

It is fortunate for the peace of mind of the stronger sex that a veil is drawn before the portals of a room in which woman fulfils her duties of maternity. Could the experience of the gynecologist and the accoucheur be known to the general public, few would face the consequences of married life.

The agony endured by women during natural labor is sufficient to account for the biblical belief that such torments are the result of a special curse of God. But what are these human pains to those involved when complications exist, beginning with the forceps and ending in the classic Cæsarean operation, as now performed in Germany without anæsthetics?

Turning from the richly furnished room of the fashionable mother, in which all the resources of civilization have been gathered to ward off the effects of luxury and ease, resulting often in the necessity of making an abdominal section and thus releasing the child; let us turn to barbaric life and observe how perfectly and painlessly the act of the reproduction of the species is performed. Lieutenant Bove, speaking of his experiences among the Jagan tribe of Terra del Fuego, says, "When the great moment arrives the future mother leaves her wigwam, accompanied by a few female friends, and seeks

a secure retreat in the woods. The very next day the young mother is often seen fishing in a canoe, or gathering shell-fish along the coast." These women marry young and are very prolific; seven, and even eight, being the average number of children.

Lieutenant Bove states that the Fuegian women lead a hard life, and are treated as slaves; but hard work, a scant diet, and plenty of fresh air seems to result in the production of very small new-born children, hence the ease of childbirth. On the contrary, luxury, ease, gluttony, and other evils of fashionable life, appears to effect an over-development of the fœtus; this combined with a weak and debilitated body may help to explain those complications in child bearing which are so often witnessed among civilized women.

AN AUTHENTIC CASE OF TYPHOID FEVER IN A MAN AGED SIXTY-EIGHT.

DR. W. G. ENGLAND, of Cedartown, Ga., writes to us regarding an alleged case of typhoid fever in a person aged seventy-two, and adds that he has undoubtedly treated a case of this disease in a patient of sixty-eight years. Dr. England sends us the notes of his case, from which there appears to be no question as to the correctness of the diagnosis. The patient had at first a gradually rising temperature, tympanitis, and iliac tenderness, the rose rash, and the cerebral symptoms of typhoid. Convalescence began in the fourth week. The fever rose as high as $105\frac{1}{2}^{\circ}$ at one time. Dr. England concludes: "When first called to this case I looked upon it as being a malarial continued fever, as we were then having an epidemic of malarial manifestations; but the evidence became so convincing that I was forced to abandon my first opinion. I determined to give quinine a fair chance to control the disease, if it would do so, as is asserted by various authorities, but soon saw that it was not meeting my expectations, therefore I abandoned it. In the past eighteen months or two years, I have treated several cases of what I considered typhoid fever, and in all of them I have given quinine a fair and impartial test, but in none has it met my expectations, and I therefore stopped its use; possibly I did not continue it long enough."

Dr. England gave quinine in three grain doses, which is not enough to secure the antipyretic effect.

THE DOCTOR AND CULTURE.

DR. J. MILNER FOTHERGILL says (*Philadelphia Medical Times*), alluding to the attainments of Sir Thomas Watson, Sir Henry Thompson, Seymour Haden, and Dr. Richardson, in other fields besides those of medicine or surgery:

"There has long existed an impression that if a medical man knew anything out of his profession he could know little of it, or at least have little acquaintance with the latter practically—an impression most unjust to many. Because a man is without other culture, therefore his intellect is completely devoted to his profession, was a view which it was convenient for a good many medical men to do their best to keep up and disseminate. But the tendency is setting the other way. If a medical man manifests good sense and acumen in other matters

of which the public can judge, they are now inclined to give him credit for like qualities in his profession—an act of justice which the public is readier to render than the medical man's professional brethren, it is to be feared."

This is eminently true, and we are not lacking in similar examples in our own country.

SCARLET FEVER IN THE NEWLY BORN.

DR. A. M. OWEN, Surgeon U.S.N., stationed at Pensacola, Fla., writes that scarlatina anginosa has been rife among the children in that locality. The disease assumed a mild form, and has been followed in but few cases by unpleasant sequelæ. He mentions an instance, however, in which the affection attacked the newly-born, an occurrence rarely observed. A younger sister of the lady about to be confined, and who occupied the same bed with her, was taken ill a few days previous to the accouchement, with what proved to be scarlet fever. The invalid was removed from the lying-in room on the day that the labor took place. Five days after delivery the baby had fever, sore throat, scarlet efflorescence, and the strawberry tongue, followed by partial desquamation of the cuticle. Before the end of the week the child resumed nursing and made a rapid recovery. The mother had a severe sore throat, as did also the nurse.

News of the Week.

REGULATING MEDICAL PRACTICE IN PENNSYLVANIA.—A bill has been prepared to amend the existing law regarding registration in Pennsylvania. It provides for the creation of a State Board of Health who shall have the supervision of registration, instead of the various colleges, as is now the case.

AN ACT TO REGULATE THE SALE OF POISONS IN NEW JERSEY.—A bill has been introduced into the New Jersey Legislature making it imperative to suitably label all drugs usually denominated poisons, placing upon each box or package the name of the articles and the word *poison*, together with the name and place of business of the seller.

THE PRICE OF QUININE has declined 10 cents, and is quoted at \$1.80 to \$1.95 per ounce.

THE TRAGEDY AT BELLEVUE HOSPITAL.—Michael Kelleher, an inmate of the alcoholic ward in Bellevue Hospital, was killed on Sunday last by Geo. E. Mahan, another patient, who was suffering from delirium tremens.

THE EFFECT OF INHALATIONS OF ETHER UPON THE ACTION OF THE KIDNEY.—Mr. Lawson Tait, in a recent communication to the *Lancet*, makes the important observation that in several cases noted by him, the excretion of urine from the kidneys was entirely suspended during the administration of ether. He observed this in a case of fistula between the ureter and cervix of bladder. Also in several cases of vesico-vaginal fistula, the same thing was noted. The observation, if true, is important. It is known, however, that ether increases the gastrointestinal secretions, and there is no *a priori* reason for believing that it always affects the kidneys as described.

THE BRAIN OF GAMBETTA.—The brain of Gambetta weighed only 1,160 grammes, or about 36 ounces. This is extraordinarily small, since the average weight of a Frenchman's brain is 48 ounces, the range being from 45 to 56. Decided microcephaly is usually considered as beginning at about 37 ounces, and Gambetta must, therefore, if report is correct, be pronounced microcephalic. The range of brain weight in idiots is between ten and thirty-five ounces, and the distinguished French statesman touched very closely upon the anatomical basis of idiocy. The convolitional development was rich and clearly marked.

It is something almost unique and incredible that a man of such brilliant intellectual attainments should have had so small a brain. It is well known, however, that inferences as to mental development cannot usually be drawn from a study of individual brain weights. The size of the brains of a race do furnish an indication of development. Highly civilized races are capable occasionally of producing what may be called physiological megaloccephaly. The lower races cannot do this to the same extent. Such at least is the most plausible of the present views regarding the significance of brain weight.

GERMAN MEDICO-CHIRURGICAL SOCIETY.—At the annual meeting of the German Medico-Chirurgical Society of New York City and vicinity, the following officers were elected for the current year: *President*, Felix Nordemann, M.D.; *Vice-President*, Charles Heitzman, M.D.; *Secretary*, Ludwig Weiss, M.D.; *Corresponding Secretary*, H. J. Boldt, M.D.; *Treasurer*, Joseph Glaser, M.D.; *Librarian*, Samuel Kohn, M.D.

IMMIGRANT INSPECTION SERVICE.—The final report of Superintendent John H. Rauch shows that a total of 115,057 immigrants were inspected in the District between June 1 and December 31, 1882. Of this number, 57,302 were found to have been satisfactorily vaccinated before sailing or during the voyage, and 3,127 were found to have had small-pox—making about 53 per cent. of the total number protected. There were 28,408 of the remainder vaccinated or revaccinated after arrival and before reaching this District; and 21,618 similarly treated by the Western inspectors, leaving 4,602 unaccounted for, including those whom it was deemed inadvisable to vaccinate.

ANOTHER CARDIAC STIMULANT.—In Russia the *adonis vernalis* is a popular remedy in cases of dropsy and heart disease. Exact experiments have recently been made with it by Dr. Babnow, of St. Petersburg. It stimulates the motor and inhibitory ganglia of the heart, acting very much like convallaria and digitalis. Unlike digitalis, it is not cumulative in its action. A glucoside "adonidini" has been isolated by Cervello; it contains the active principles of the drug.

CHOLERA IN SOUTHERN MEXICO.—A recent letter from Chiapas, one of the southern States of Mexico, gives a pitiable account of the havoc being wrought there by cholera. The writer says: "The town of Tuxtla had eight thousand inhabitants—six hundred of whom are dead. Of the six thousand in Tonala, upward of one thousand are dead. This town suffered most severely,

twenty to thirty persons dying daily. This horrible epidemic broke out in July, 1882, on a farm bordering on the River Chiapas. Then it extended to San Bartolo, where it worked havoc for a month, and then moved onward, visiting Chiapas and Tuxtla, almost on the same day. It remained in those towns about twelve or fourteen days, and then went toward Tehuantepec. Then it penetrated to the Atlantic, and caused many deaths in Tabasco and other places. It is certain that it is a disease that only affects the hottest regions, as not a case occurred in San Cristobal Las Casas."

TOBACCO-SMOKING AMONG AMERICAN BOYS.—The head master of the Latin School at Boston, Mass., states that tobacco is used by half the boys in the upper classes in his establishment, while the Principal of Harvard Grammar School, in Charlestown, avers that out of 300 boys, about 40 per cent. use tobacco habitually.

DR. CHEW KIN FONG.—It is darkly hinted that New York physicians may yet be ruined by Chinese cheap labor. A Chinese physician, Dr. Chew Kin Fong, who enjoys a large practice among his fellow-countrymen here, has recently applied to the Board of Health for recognition. He could talk no English, but showed a certificate issued by the Harbor Department, Hong Kong, and affirming his qualifications as surgeon of a Chinese emigrant ship. The certificate was not recognized, and Dr. Fong will have to be examined. Assuming that he passes, the serious question arises whether it would be proper to consult with a person who practises, it is said, on strictly oriental principles.

BACILLUS OF TUBERCLE IN THE BREATH.—Dr. Arthur Ransome has recently announced before the Royal Society that he has been able to discover the bacillus tuberculosis in the condensed aqueous vapor of persons afflicted with phthisis. This is a new source of alarm, if Koch's malignant bacillus can be puffed in our faces by all our phthisical cases.

A NEW HOSPITAL at Dayton, O., has recently been completed and opened. It cost \$75,000, and has a capacity of 200 beds.

THE PARIS FACULTY OF MEDICINE.—The Faculty of Medicine now comprises four separate departments: the ancient Faculty, the Practical School (which is temporarily lodged in the buildings of the former College Rolin), the Botanical Garden of the Rue Cuvier, and the Clinical Hospitals. The number of students who followed the course of lectures for the last year (October 16th, 1882 to 1883) was 4,209, this being exclusive of fifty foreigners and thirty-nine women, the latter being thirteen fewer than last year. The number of examinations at the Faculty of Medicine was 6,076, nearly a third of whom were "plucked."

A NEW PRIZE.—The French Government has recently resolved by decree to found a prize, to be called the Prix Volta, and of the value of 50,000 francs, which shall be awarded for the most successful application of electricity, either in the production of heat, light, chemical force, or mechanical power, or in the transmission of messages, or in the treatment of disease. Competitors may be natives of any country, and claims to the reward must be lodged by June 30, 1887.

Progress of Medical Science.

THE HISTOGENESIS OF CARCINOMA.—Dr. Carl Hempel Reed, in the *Philadelphia Medical Times*, reports the results of some studies in the Pathological Laboratory of the University of Pennsylvania, upon the histogenesis of carcinoma. He concludes that cancers have an exclusively epithelial origin, and summarizes the essential points in favor of this view as follows: 1. Primary true cancers are found only in locations where there is pre-existing epithelium. 2. No cancer has been proved beyond doubt to have originated heterotopically. 3. The cicatrization of cancers explains the young connective-tissue infiltration. 4. Young connective-tissue cells or white blood corpuscles never being seen inside the alveoli. 5. The independence of the epithelial cancer-cylinders from the connective tissue. 6. The intactness of endothelial ensheathments of connective-tissue trabeculae forming the alveoli. 7. The mode of development and concentric growth of secondary cancers. 8. The proliferating power of epithelium normally is greater than that of any other tissue. 9. The results of my experiments showing that the epithelial covering in the healing of ulcers is exclusively derived from the epithelium of the border, a most conclusive proof of this being the gradual advancement of the pigment from the borders of the healing ulcer; this fact, by analogy, forming a strong testimony in favor of the epithelial origin of cancer. 10. The transformation of connective-tissue cells into epithelial cells, in extra-uterine life, does not occur, either physiologically or pathologically.

MERCURIAL GLYCERITE.—Dr. Vigier states (*Gazette Hebdomadaire de Médecine*) that medicinal agents, incorporated with fatty substances, are absorbed to only a limited extent. Mercurial ointment, however, forms a noteworthy exception to this general rule. Drugs incorporated with glycerine are, according to Vigier, not at all absorbed. He considers that this property of glycerine is due to its not wetting the skin. Experiments on himself and his pupils have proven that the active substance thus incorporated never produces its constitutional effects. It is for this reason that he recommends glycerine instead of lard in mercurial preparations for scabies, pediculi, etc., as such a mixture has an antiparasitic effect without being absorbed. The following glycerite, notwithstanding the caustic nature of its principal ingredient, he says, may be used without danger:

R. Hydrarg. bichlorid. 3 iss.
Glycerine 3 iij.

M.

THE ENDERMATIC USE OF QUININE IN MALARIAL PNEUMONIA OF CHILDREN.—Dr. L. Galanti, of Rome, applies an ointment of sulphate of quinine to the raw surface produced by blistering, in the malarial pneumonia of children. By this means he avoids the difficulties often encountered in the internal administration of this drug.—*Gazzetta medica di Roma*, No. 19, 1882.

WASHING OUT THE STOMACH WITH CHLOROFORM WATER.—Dr. Aurelio Bianchi, reports three cases in which he employed chloroform water, in the proportion of one drachm of chloroform to a quart of water for washing out the stomach. The first case was one of supposed cancer of the pylorus, and is claimed to have been much benefited by this procedure. The two others were instances of chronic dyspepsia, and are said to have been cured.—*Lo Sperimentale*, No. 10, 1882.

LYMPHADENITIS OF THE CONJUNCTIVÆ.—Dr. W. Goldzieher, of Buda-Pesth, Hungary, recently removed from the conjunctival cul-de-sac of a fourteen-year-old boy a hard, painless tumor the size of a filbert. On the surface of this growth were to be seen yellowish, cheesy-looking plaques, which apparently penetrated into the

depth of the tumor; whilst in other places small, round, grayish nodules could be made out through the translucent mucous lining. There was a family history of scrofula. Dr. G. first thought that it was a case of tuberculosis of the conjunctiva, but the microscopic examination of the specimen showed that it was an enlarged lymphatic gland. The existence of lymph-follicles in the normal conjunctiva, though vouched for by some microscopists, has been strenuously denied by others. The present case would seem to afford corroborative evidence of the real presence of these conjunctival follicles.—*Centralblatt für Praktische Augenheilkunde*, November, 1882.

HYDROTHERAPY IN THE TREATMENT OF SYPHILIS.—Dr. Pascal advocates the employment of cold water, conjoined with the internal administration of specific remedies, in the treatment of syphilis. He states that it is of great service in the early stages, by virtue of its tonic effects, in overcoming syphilitic anæmia. In the later stages it is employed with advantage in the various cerebral accidents of specific origin. He condemns the thermal baths, however, as tending to cause the very cerebral complications for which the cure is sought. The cold bath alone is of little utility, but should always be regarded as an adjuvant to internal medication.—*Journal de Médecine de Paris*, No. 15, 1882.

DIABETIC COMA.—Drs. Foster and Saundby record a carefully studied case of diabetic coma in the *Birmingham Medical Review*, January, 1883. They have summarized their conclusions as follows: 1. Diabetic coma is especially liable to supervene in acute cases in young persons. 2. Diabetic patients and their friends should be warned of the danger of constipation, muscular exertion, nervous excitement, and cold, as probably predisposing causes of death by coma. 3. The discovery of the ferric chloride reaction in the urine should be taken as a warning to look out for the premonitory symptoms of coma. 4. Deep respiration, rapid pulse, and abdominal pain are the earliest premonitory signs of this condition. 5. Cyanosis may be absent in spite of the dyspnoea, and may appear only just before death. 6. Convulsive seizures are not an uncommon occurrence just before death. 7. Diabetic coma, with all its classical symptoms, occurs independently of any excess of fat in the blood, and the pathological value of lipæmia, when present, is yet undetermined. 8. The toxæmic theory, or poisoning by acetone or some nearly allied substance or substances, affords the best explanation of this remarkable group of symptoms.

STRANGULATED HERNIA, COMPLICATED BY DISEASE OF THE SPERMATIC CORD.—Dr. John L. Atlee reports in the *American Journal of the Medical Sciences* for January, 1883, a case of strangulated hernia, in which the scrotum was enormously enlarged; at the bottom it was twelve inches in circumference, and came down nearly half way to the left knee. The surface of the scrotum was marked by numerous large and very dark veins. The bulging at the external ring was as thick as the wrist, and no impression was made by the taxis. When the sac was opened the first thing that presented was a large mass of omentum running down to near the bottom of the scrotum. This was raised up, and a knuckle of intestine, ilium, about five inches in length, firmly strangulated and of a dark mahogany color, but with no ash-colored spots. After the reduction of the hernia from the ring proceeded a cord as thick as a lead pencil for about three inches. It then became much thicker and highly vascular, resembling the omentum, which he had already removed. There was a large mass lying in the very bottom of the scrotum, in some places nearly as thick as a bantam egg, with many smaller lumps extending down the mass, and fringed with highly vascular membranes; when drawn out it measured eighteen inches in length, and weighed twelve ounces. As it approached the testicle it became as small as at its origin in the

ring. He found the testicle wasted and very soft and firmly attached to the bottom of the cavity. The conclusion was drawn that it was an immense hypertrophy of the cord and epididymis, and it was concluded to remove it, which he did after tying at the ring above and at the testicle below. After plugging up the ring with the stump of the omentum and cleansing the empty sac, he closed the external wound and applied a bandage. The patient bore the operation well.

CANCER OF THE TESTICLE FOLLOWING ORCHITIS.—At the recent meeting of the Rhode Island Medical Society, Dr. Fuller narrated a case of carcinoma following orchitis. The patient, aged thirty-four, had chronic orchitis for twenty-two years caused by a blow on the testis when a lad of twelve years. Four months before removal the tumor became painful and rapidly increased in size, adding one-third to its bulk in four months.

Excellent recovery from the operation, and immediate recurrence in the abdominal cavity, forming a tumor the size of a man's head, and causing death in two months.

The upper two-thirds of the tumor was fibrous, and contained cysts and enchondromatous masses. The lower third was encephaloid. The abdominal tumor was also encephaloid.

LARGE DOSES OF ALCOHOL IN SCARLATINA.—At the last meeting of the Academy of Medicine of Cincinnati, O., Dr. Giles Mitchell reported forty-three consecutive cases of scarlatina treated with large doses of alcohol, without a single death. The quantity of alcohol given in some cases was enormous. To a patient two years old a half-ounce of whiskey was given every hour for a number of days, without having any other than a favorable effect, and without producing any symptoms of alcoholic intoxication. The doctor claimed that when this treatment was instituted, the disease had always pursued a more favorable course, hyperpyrexia being neither so frequent nor so prolonged, nor were renal complications so likely to ensue. In case the kidneys became affected, the alcohol was still pushed, and the complication fully relieved. If the temperature was high before the administration of the remedy, it would rapidly fall below the danger-line after the treatment was instituted. The report of Dr. Mitchell called forth a lengthy discussion from the members of the Academy. Prof. Whittaker thought that the favorable influence exerted by the remedy was due to its antiseptic properties. He had no doubt that the brilliant results obtained were due to the antiseptic and parasiticidal properties of alcohol, as manifested in these cases by the destruction of the germ of scarlatina. Prof. Reamy was a firm believer in the efficacy of large doses of alcohol. He attributed its good effects rather to its influence in preventing tissue-metamorphosis, to its value as a food, and to its antipyretic action.—*Philadelphia Medical Times*, December 30, 1882.

RENAL SURGERY.—In its annual retrospect of the advances made in medicine during the past year, *The Medical Press*, December 27, 1882, makes the following comments on this subject: Several operations for removal of renal calculi, and for relief of symptoms set up by presence of pus in the organ, have been recorded, the majority eventuating successfully. Nephro-lithotomy, as performed by Mr. Morris, has been repeated by Mr. Beck, who points out that favorable subjects for the operation should not be too fat, and that when pus in the urine affords indication that the stone in the kidney is setting up irritation, then the time for operative interference has arrived. Mr. Beck repeats what Mr. Morris pointed out in respect to the bleeding from the incised kidney. Though seemingly very profuse for a moment, it is at once and permanently controlled by the pressure of a sponge, and does not subsequently seem to cause embarrassment.

From the numerous cases reported before societies and

in journals, in which grave operations on the kidney have been attended with success, it is evident that an increasing feeling of hope as to the consequences of such interference is growing up among surgeons, who will now proceed to cut into or remove a kidney with much less hesitation than would have been shown a few years ago. The most hopeless cases of this kind that are met with now are those extreme examples of degeneration in which the kidney is little more than a sac containing pus, and which yield the least likely of all probabilities of successful removal of the mass. A very considerable number of cases in which operative treatment for removal or evacuation of diseased kidneys has succeeded have been reported during the year, and it is a justifiable conclusion, from consideration of these proceedings, that a much more evident willingness to attempt to give relief to patients by such measures is exhibited now than formerly. In fact, this may be said of surgical operations generally. Many which are now by no means uncommon would have been promptly rejected not very long ago, as involving an amount of risk not justified by the probabilities of success or even of relief to distressing symptoms.

SUPERINVOLUTION OF THE UTERUS.—Dr. Sinclair, at a meeting of the Boston Obstetrical Society (*Boston Medical and Surgical Journal*, December 21, 1882), reported a case of what he regarded as uterine superinvolution. The woman was twenty-six years old, and, after the third child-birth, she ceased to menstruate. Although plump and well, she was very nervous. There had been no menstruation for a year when she consulted Dr. Sinclair, who found an extremely small, infantile uterus. This would not admit a small uterine sound, but a probe could be passed up two and a half inches. She is now thirty-six years old. A year ago the husband had called to say that his wife was in charge of a physician who said that the trouble was due to a ruptured perineum and lacerated cervix. Dr. Sinclair claimed an examination in his own defence, and found no laceration whatever.

A NEW OPERATION FOR SPINA BIFIDA.—At a recent meeting of the Leeds Medico-Chirurgical Society (*British Medical Journal*, December 30, 1882), Mr. Robson showed a child six weeks old, upon whom, when six days old, he had performed a new operation for spina bifida. The redundant parts removed by the operation were also shown. After the removal of these parts and after stitching up the arachnoid over the spinal canal, periosteum from a rabbit was inserted between the meninges and the skin so as to cover the gap in the bones. The wound had perfectly healed; the skin over the lumbar region was quite level; there seemed to be no tenderness on pressure; the child looked strong and healthy. The sac was found to be of the size and shape of half a swan's egg; the wall consisting of true skin and subcutaneous tissue lined by serous membrane. At one point the sac was very thin and transparent, appearing to consist only of the serous membrane covered by a thin layer of epidermis, when fresh minute blood-vessels could be seen to ramify over it. Mr. Robson drew attention to the following points: 1, the operation was performed with full antiseptic precautions, eucalyptus air being used instead of carbolic spray; 2, the meninges were closed by uniting the serous surfaces, as in peritoneal surgery; 3, the transplantation of living periosteum and its continued vitality; it had not yet, however, formed new bone, but already the covering of the canal had a greater than mere skin-firmness; 4, the entire absence of bad symptoms in the child, operated upon at so early an age, was noticed.

ETHYL BROMIDE INTERNALLY FOR SPASMODIC COUGH.—Dr. Squire recommends a solution of bromic ether in water (1 to 200) for administration in whooping-cough, as well as for angina pectoris and spasmodic pain. It may be given in the same manner as the aqua chloroformi of the British Pharmacopœia.

Correspondence.

THE TREATMENT OF ASTHMA.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR: By practising in strict accord with accepted pathological data, pure spasmodic asthma may be radically cured. In the treatment of this commonly intractable disorder I have met with such success that I now assume charge of asthmatics with a feeling of pleasure, confident of the relief so sure to come.

In THE MEDICAL RECORD, over two years ago, I pointed out the striking fact, that *counter-irritation applied over the pneumogastric nerves*, from the upper part of the thyroid cartilage to near the upper borders of the clavicles, stopped paroxysms of asthma. I detailed the case of a lady, aged fifty years, afflicted with that disease nearly all her life, and whom I had attended at times for over three years, and to whom I was last called on April 1, 1880. On that day commenced the most violent attack of asthma she ever had. Until May 10th she had never left her room—scarcely the chair in which she sat. Morphine alone quieted her continued dyspnoea, and to diminish the quantity was only to increase the dyspnoea. At last, but semi-conscious, extremely weak, with face and limbs greatly swollen, and the head fallen forward on her chest, I feared dissolution.

Her case was one of pure 'nervous or spasmodic asthma, a disease in which I recognize two pathological elements: 1, *nervous spasm* of the bronchial tubes; 2, *hyperæmia*, approaching or amounting to inflammation. Difficult breathing involves all the physical signs. The *râles* have a *double character*; *id est*, they occur *both in inspiration and in expiration*. This I recognize with Professor Alonzo Clark as a *sure sign* of spasmodic asthma.

In this affection I have relied on morphine most of all; then nauseants and antispasmodics *ad infinitum*. But nothing longer benefited my patient. I was perplexed, when at last the idea arose in my mind, and with Churchill's tincture of iodine I applied counter-irritation over the course of the pneumogastric nerves. Relief followed so rapidly and absolutely as to make me doubt that it was due to my application. Benefited in less than twenty-four hours, freedom from asthma was absolute in less than forty-eight. I determined to paint again so soon as the paroxysm returned. It never returned.

In June I applied the same treatment to two more cases, with the same happy result. And up to that time all I had observed was relief of the paroxysm, and only of the first, because no patient had any return of them after the one application of iodine. Those three cases were placed upon iodide of potash internally for a short time. Not one of them, to my knowledge, has ever had a return of the paroxysms.

Apropos of my report in THE RECORD, my friend, Dr. J. M. Lee, of Pittsburg, mentioned to me a case in his service at the Mercy Hospital, of uncomplicated spasmodic asthma so severe that he had become alarmed for his patient's safety, when Dr. T. C. Christy called his attention to my article in THE RECORD, which he had that evening received, and suggested "that Faulkner's plan be tried." Dr. Christy's suggestion was acted upon, and Dr. Lee reports the effect to have been "brilliant;" relief came rapidly and completely. The man unceremoniously left the hospital next day, remarking that "he was well and there was no use in remaining longer."

Again, in February, 1881, my friend Dr. James B. Murdoch was pleased to draw my attention to an article in *The British Medical Journal*, by Dr. Robert Saundby, in which, having adopted my plan and terming it "the iodine treatment of asthma," wrote as follows: "H. H. had suffered for the last six or seven years from attacks of dyspnoea, coming on at three o'clock A.M., which for-

merly occurred only in June or July, but latterly throughout the year. I painted the lines of both pneumogastrics with a mixture of equal parts of the liniment and tincture of iodine and ordered him to repeat it every night. The next time I saw him he told me that he 'had not had such a good night's sleep for twelve months.' He slept all night, and was so surprised upon waking in the morning that he got out of bed to look at his watch before he would believe it. He discontinued the iodine after a few applications, as the skin became sore, but he has had no return of the attacks."

Since my first successes in the treatment of this malady, I have studied with interest and quite peculiar favor the disease in its several bearings upon thirty-seven cases: 1st, regarding constitutional differences in asthmatics; 2d, regarding treatment of occasional complications; 3d, regarding climate and change in residence. Close observation has led me to think that one great source of failure in treatment is to be found in insufficient consideration of constitutional variations. The treatment of a name, in lieu of pathological condition, has never been more impotent than in asthma. Little meditation is required to show that tall, thin, anæmic patients need different management from short, fat, full-blooded. Obesity must be reduced by hygienic means, by diet, laxatives, exercise. Slender and emaciated patients must be strengthened by wholesome food, by tonics, such as iron, strychnine, digitalis, cod-liver oil, phosphorus, exercise.

In common torpidity of the bowels, regularity in function is often insured by a pill at bedtime, containing one grain each of blue mass, rhubarb, purified aloes, and extract of hyoscyamus. In many asthmatics there is depreciation of the nervous system. And then my reliance is upon cod-liver oil. Useful, too, are iron, arsenic, phosphorus. Strychnia seems especially beneficial in giving fillip to the muscular fibre of the bronchial tubes, aiding expectoration. Fits of sneezing and eruptions upon the skin give assurance for the administration of arsenic. Bronchial congestion requires iodide of potash. The skin of most asthmatics is so impressionable to atmospheric changes as to require particular attention. To strengthen the skin, I consider a cardinal point in the treatment of asthma. And for this purpose I administer salt-water baths, by seating the patient upon a cane-bottomed chair, and throwing over him a blanket, fastened around his neck and covering the chair, underneath which is placed an ordinary or Bumstead evaporating pan with spirit-lamp, the pan containing about three ounces of water and a heaping teaspoonful of salt. As soon as the sweat has freely broken, the patient is rapidly shampooed, rinsed with pure, cold water, carefully dried, and then rubbed until the skin glows. I sometimes find it weeks before I can make it glow. But I persevere. The bath I order repeated twice a day, daily, or every alternate day. Its advantages can scarcely be told.

Another cardinal point in treatment is inflation of the lungs: 1, to increase or restore the natural breathing capacity; 2, to cleanse the bronchial tubes and air-cells of secretion. This I do not attempt with the extravagant apparatus of Waldenburg, but with a simple and inexpensive Politzer's inflator. It answers admirably. Asthmatics are short of breath because of spasm, and partly because of diminished breath space. Now air forced into the lungs expands the tubes, dilates the vesicles, and is followed by free expectoration and comfort. The patient is directed to take as long an inspiration as possible; then the nozzle of an inflated Politzer bag is inserted between the closed lips, the nostrils held, and the bag compressed. Thus do I force into the lungs at every inspiration from one to three bagfuls of air, and continue this process for ten minutes, and repeat it morning and evening. Professor J. C. Dalton says that "the average amount of air inhaled at each inspiration is twenty cubic inches, and that representing from ten to

thirteen per cent. of the entire quantity of air in the lungs, it will therefore require from eight to ten respirations to change the whole quantity of air in the cavity of the chest." An ordinary-sized Politzer's bag will hold about ten to eleven cubic inches of air. Remembering these facts, we know the quantity of air which can with safety be forced into the lungs, and also have a gauge whereby to tell the amount of improvement made in the dilatation of the air-vesicles and small tubes, or in other words, of the increase in "vital capacity of the lungs."

To a change in the residence of asthmatics I object, because the benefit so derived is generally only temporary, the malady soon returning in the new residence. And it is reasonable to suppose, not even considering the expense of travel that patients can be managed better at home by men, to whom, as Jacobi philosophically remarked, "the science of medicine is no longer mere formula, and its art no routine," than by charlatans, so numerous at all "resorts."

It has been insisted upon by great authorities that an urban residence is best for asthmatics, and more especially that portion of a city in which the atmosphere is heaviest and smokiest. That I cannot believe. Smoke and heaviness are synonyms for fog and dampness. I dissent, because here in Pittsburg, where the atmosphere is the smokiest, heaviest, and as such, of largest area on the continent, we have, I dare say, more native asthma, and from it a death-rate, great, if not greater than that of fairer cities, in which there is a pure atmosphere, dry, warm, and of nearly equable temperature. No one ever visited Pittsburg without complaining, almost within an hour of their arrival, of the "dirt" in their throat and the blackness of their nostrils. There is a faucitis peculiar to Pittsburgers. The sulphur-charged atmosphere is irritating to the delicate mucous membrane of the eye, nose, throat, and bronchi, and produces a chronic congestion, the secretion of which catches and holds to view the carbonaceous material of the atmosphere. The inspection of the oral cavity of every resident reveals its secretion charged with black, carbonaceous material. This carbon, drawn in with every inspiration, affects alike the mouth, throat, and chest, as I have seen upon post-mortem examination. The inhalation of the smoke of Pittsburg is not conducive to health.

True, there are some asthmas benefited by Pittsburg residence, but only, I believe in accordance with the fact that travel and *change* will bring relief—the centres of relief being, however, elsewhere as well as here.

On the whole, I judge the opinion of preference for city over country residence to be mainly traditionary, and due to failure in differentiation of the forms of asthma.

Yours, etc.,

RICHARD B. FAULKNER, M.D.

PITTSBURG, PA.

DISINFECTION BY HOT AIR.—Koch and Wollhügel, in experiments made to determine the disinfecting power of hot air, have been led to the following conclusion: 1. Bacteria are destroyed by being exposed to a temperature of a little over 100° C. for an hour and a half. 2. Spores of brewers would require for their destruction an exposure for the same time at 110–115° C. 3. Bacilli are killed only by three hours' exposure at 140° C. 4. The heat of hot air penetrates articles so slowly that in three or four hours' heating, at 140° C., of small objects, such as a bundle of clothes, etc., disinfection was not secured. 5. Five hours' heating at 140° C., necessary to certain disinfection, does serious injury to most articles.

On the announcement in Russia that the course of medical instruction for women would be closed, a great meeting was held to protest against the measure, and a Moscow merchant offered to spend 200,000 roubles if the St. Petersburg authorities would undertake the management of the lectures.

New Instruments.

IMPROVED GENERAL EXTENSION SPLINT FOR LOWER EXTREMITY.

By A. CLENDINEN, M.D.,

FORT LEE, N. Y.

THE splint may be said to be composed of three sections. First, the main section, constituted by extension and counter-extension rods Nos. 5 and 6, with their reverse tractors Nos. 8; tractive lines through ringlets, over brass rollers; of centre brace No. 10 to cross bar No. 11, with fixation or check line No. 9, and suspension line No. 11. Second, the pelvic section or attachments Nos. 1, 2, 3, and 4 with ischio-pubic and abdomino-lumbar bands attached to ringlets, as seen in cut. The ringlet in No. 3, for the attachment of ischio-pubic band, is within three

inches of point of attachment to main section, while the ringlet at and in No. 4 is six inches from point of attachment to main splint where shown by the nut of bolt in plate. This difference is necessary to conform band to the pelvic lines and obtain easy bearing and even fulcrum. Third, is the foot section 7, with attachment, as seen by the bolt nuts opposite ankle, which is the point of its attachment, and where by the temporary withdrawal of one of the bolts, hinge motion can be had for the prevention of ankylosis, when feared. Centre ringlet is in the end of foot-piece, for attachment of plasters from foot and at each corner, for guy lines. This splint is made of unannealed wire, is simple, cheap, and easily portable.

The patient is supposed to lie upon a *level* surface, with the exception of pillow for head. On upper section of bed lay an extra two inch thick mattress, reaching to the buttock. In suspension of limb use as little elevation as possible, viz., have the limb's heel within four inches of the level bed surface of the first mattress. By so arranging, the limb is in about natural line with body,

and yet we have obtained room for use of bed-pan and removed any chance of fouling the dressings. The splint which has been suspended is now held over the limb in order to open or close the tractors 8, so as to maintain proper width just to clear diameter of limb, and at the same time the foot-piece is bent to the same width, so that the side lines will be parallel, in avoidance of friction. Piece No. 3 should now be bent to suit the rise over mons veneris and abdomen, and the same must be done with pieces 1 and 2, which are coupled, for the purpose of enabling them to be used in application to either side and to avoid much bending. Whichever of the ringlets of No. 2 piece reaches No. 4 is now coupled with bolt. The fixation line 9 is so tightened that the tractors 8 cannot displace the extensor and counter-extensor rods, which remain their entire length side and side, the ringlet hook at either end being in juxtaposition to the bolt nuts seen in plate where the pelvic and foot attachments are connected. After felting or other dressing has been applied to abdomen, etc., the splint, to off side of which the bands and plasters have been fastened, is lowered, and the surgeon draws under limb the plasters to the near side, and by pins adjusts the same to the proper rod, viz., those plasters applying to the upper fragment will be fastened to the counter-extension rod, and those of the lower fragment to extension rod. By so doing we avoid friction and get the benefit of full weight of limb for the extension of its lower fragment. The plasters are now adjusted to foot, etc., and attached to the foot-piece; the ischio-pubic and the abdomino-lumbar bands are made taut, and the suspension cord is drawn to the proper elevation of limb. Measurement is made, shortened estimated, and the fixation cord 9 is slackened to allow the tractors 8 to effect the extension, while digital and eye attention to the line of fracture will decide surgeon when to order the tightening of No. 9 cord. His judgment must be confirmed by comparative measurement and allowance for articular separation, and to overcome excessive muscular spasm extra traction may be judged temporarily necessary, and can be held by fastening the tension lines at 10. Measurements should be made and remade during the first fourteen days, and at the different periods not only spasmodic tension but muscular relaxation and atrophy judiciously accredited. Extra antagonistic bandages can be used in oblique and other fractures.

THE HEALTH OF BROOKLYN.—The report just published of Health Commissioner Raymond, of Brooklyn, comprises a record of eleven months ending November 4, 1882. During that period there have been 15,092 deaths, or 559 in excess of the actual mortality in the year 1881. No cases of small-pox were reported since the first week in September, due to the fact that house to house vaccination has been systematically enforced. Dr. Raymond very earnestly and very properly urges the establishment of a hospital in that city for the reception and treatment of persons suffering from contagious diseases.

REMOVAL OF A LARGE BRONCHOCELE.—Dr. Cheever, of Boston, removed, quite recently, a large bronchocele at the Boston City Hospital. The tumor weighed ten ounces. The right and left lobes were dissected in turn from their beds by the usual incisions, and the thyroid and other arteries tied before they were severed. The amount of blood lost was inconsiderable, scarcely equalling eight ounces. The patient subsequently died of shock at the end of twenty-four hours.

PERFORATION OF NASAL SEPTUM.—Dr. John B. Roberts, of Philadelphia, has invented a punch for cutting out a disk of cartilage in cases of nasal obstruction due to deviated septum. He does not consider the prevalent notion that the partition between the nostrils must not be perforated in efforts to render the occluded nostril patulous as well founded.

Reviews and Notices.

ON THE NATURE AND TREATMENT OF GOUT. By DR. W. EBSTEIN, Professor of Internal Medicine, and Director of the Medical Clinique in the University of Göttingen; with atlas containing five quarto chromolithographic plates. Wiesbaden, 1882.

THIS work is dedicated to Prof. Henle, in commemoration of the "Jubiläum" held in honor of the fiftieth year of his doctorate; and forms, as the author of this really thorough book modestly says, "an attempt to give a history of the physiological changes in gout, which will furnish an explanation of the clinical features of the disease."

The particular aim of the writer is, however, to show that the gouty symptoms are a necessary effect of the presence of uric acid in the blood. The discovery of uric acid by Scheele in 1776, and the proofs furnished by Wollaston in 1787, that the gouty concretions contain uric acid, did not place the proper significance upon the relation which this acid bears to gout; even Henle regarded it as an accidental product, and Garrod, in 1848, was the first indisputably to prove the presence of urate of soda in the blood of gouty patients; from his time on could we speak of a uratic arthritis.

Our author attempts to solve the many still open questions by means of experiment and anatomical investigations, and finally reaches the conclusion that in gout the disturbances of nutrition in the tissues are primarily caused by the *fluid neutral urates* circulating in the blood; the crystallization of these salts as acid salts, and their deposit in the tissues, being a secondary effect. The free acid necessary for this transformation is formed in the necrosed tissues, and consequently is an effect of the necrosis, which, in its turn, has been produced by the fluid neutral urates circulating in the blood.

A piece of blue litmus paper, placed between the cut ends of a necrosed cartilage, turned red. Whilst part of the uric acid is deposited in various localities (kidney, cartilage, tendon), but is particularly formed, according to the author, in the muscle and bone marrow of the affected extremities, another part passes into the blood and causes in the different tissues and organs manifold disturbances (visceral, retrograde, vague gout). Therapeutically the author recommends diet regulation; fat accumulation to be avoided; meat and a certain quantity of fat are permissible, while hydrocarbons and alcohols should be reduced to a minimum. Mineral waters are occasionally to be advised.

The excellent matter contained in this work is made the more comprehensible by the chromo-lithographic plates, which also artistically deserve the highest praise.

The investigations are original, the results new, and divergent from the doctrines now held on this subject; the book is therefore to be highly commended to the general practitioner as offering new and original views in regard to the protean manifestations of this disease.

ANATOMICAL TECHNOLOGY AS APPLIED TO THE DOMESTIC CAT; An Introduction to Human, Veterinary, and Comparative Anatomy. With Illustrations. By BURT G. WILDER, B.S., M.D., and SIMON H. GAGE, B.S. New York and Chicago: A. S. Barnes & Company. 1882.

THIS work is intended as a manual for the instruction of persons studying, or intending to study medicine, comparative anatomy or physiology.

Its peculiar features are, that it assumes no previous knowledge of anatomy; its descriptions are based upon the domestic cat; these descriptions are very direct, simple, minute and practical. Directions for dissection, preservation of material experimentation, and proper instruments are given, and a new system of anatomical nomenclature is introduced, which makes the work very technical in character.

The book is chiefly designed for beginners, yet it contains many references and suggestions of great value to teachers.

The descriptions are for the most part of macroscopic structure.

The book bears the mark of much conscientious labor and thorough familiarity with its subject. We can most cordially commend it as filling a place in text-books hitherto unoccupied.

The only feature of the work which calls for special criticism, is the nomenclature adopted. To this subject Dr. Wilder has given great attention, and his views are already quite generally known. His object is so to change our anatomical names that they will equally apply to all vertebrates and be equally intelligible in all nations. He therefore substitutes Latin or Greek names for some organs at present badly named, and uses words of a more general application in his descriptions. Some of the changes may be indicated. Thus, as regards names indicative of relative position, we have cephalic, for upper or anterior end; caudal, for lower; dorsal, for back or posterior; ventral, for front or anterior; sinistral, for left; dextral, for right; mesal, for median; ectal, for external; ental, for internal.

The suffix "ad" is used to turn the above adjectives into adverbs. Thus one surface is entad, or placed internally as regards another.

The change in the nomenclature of certain parts of the body is very great. Thus for the upper arm the name is brachium; for the arm, ante-brachium; for wrist, carpus; then metacarpus, pollex, index, medius, annularis, and minimus.

Dr. Wilder speaks of holding a frog between the pollex, index and annularis, then "dorsiventing" it.

There are some things which are good in themselves, but whose value we must question simply because they are impracticable.

Dr. Wilder's nomenclature, or at least the view on which it is based, is correct, and we believe would be a help to comparative anatomists. But there will long remain obstacles very nearly insuperable toward applying it to the human body. Human anatomy is a practical, and almost a popular science, in the sense that its terminology is part of our literature, and a knowledge of it part of a general education.

We must make one more criticism, and it is this: Dr. Wilder has undertaken to do what should have been done by some national or international body. The nomenclature of one individual will never be universally accepted. Although Wilder's is probably the best so far offered, the human mind is peculiar, and we doubt if a single comparative anatomist will accept it *in toto*. It is a good step, however, in unifying the present grotesque and fortuitous system of naming and description of the animal body.

The book is well printed, and is copiously illustrated with excellent cuts.

CHROMATOPTOMETRICAL TABLE. By DR. OLE B. BULL. Christiania: P. T. Mallings Boghandel. New York: Wm. Wood & Co.

THE methods which have hitherto been offered to the profession for the examination of the qualitative and quantitative perception of color have been so laborious and complicated that they have not come into general use, even among specialists. The chart constructed by Dr. Bull is intended to afford a convenient means of testing and recording the color sense (*C*) of eye patients by a practical and expeditious, though not over-scientific method. It shows ten rows of small colored squares, each row representing a different degree of saturation as expressed by printed figures. These figures enable one to record the power of quantitative distinction of color in a similar way as *V* is recorded after being tested by Snellen's test types.

Dr. Bull's chart, though scarcely adapted to work out

the difficult problems presented by cases of congenital color-blindness, will be very useful to the busy eye surgeon in tracing the progress of the different diseases of the retina and optic nerve.

SECOND ANNUAL REPORT OF THE STATE BOARD OF HEALTH OF NEW YORK. Albany, N. Y.

THIS report is a work of great value and interest. It is, we believe, by far the best that any State Board has yet produced. The amount of scientific work which its contents represent, is indeed too great for any adequate notice here. It is but due to the Board and our readers, however, that we point out the chief features.

The reports made regarding the prevalence of disease, and upon sanitary organization, relate to the year 1881, and much of what is said is now old, and has been already noticed. It is sufficient to say, that the organization of local health boards, and the registration of vital statistics, has progressed in a most satisfactory manner. We note, also, that the sanitary arrangements for school-houses have been investigated and improvements extensively made. Also, that during the past three years there have been built in New York City, tenement and apartment houses sufficient to accommodate one hundred thousand persons, all upon plans previously submitted to the local health authorities.

Over one hundred pages of the present volume are devoted to the report of the standing committee on school buildings and the hygiene of public schools, together with special reports by Dr. D. F. Lincoln and Dr. C. R. Agnew. These documents constitute a valuable source of information upon all matters relating to this branch of sanitary science.

The report upon quarantine is of more public importance than of direct interest to the medical reader.

Dr. E. H. Janes contributes a report on the outbreak of typhus fever which occurred in New York City in 1880-81.

The Report of the Committee on Drainage, Sewage, and Topography, with supplementary reports on Methods of Sewage for Large Cities and Villages, and on Effluvia Nuisances, occupy one hundred and more pages. They include a study of the various malarial regions of the State, and a history of the Hunter's Point nuisances. The best and simplest methods of disposing of sewage in small towns, are also described.

The most interesting portion of this volume to the medical man, is the part containing the reports of the Sanitary Committee, of which Professor Chandler is Chairman. These reports relate to the purity of drinking waters, the testing of inflammable oils, and the adulterations of food and drugs.

Dr. Elwyn Waller gives the results of the analyses of about forty specimens of drinking water taken from different parts of the State. Of these, 24 were pronounced bad, and 10 unsatisfactory. It is admitted, however, that there are no absolute criteria for drinking-water, and probably at the present day, the nose and eye are as good tests in most cases as the reagents of the chemist.

With regard to inflammable oils, Dr. Arthur H. Elliott states that in New York City in 1880, there were 103 fires out of a total of 1,783, due to kerosene oil; 54 of these were due to explosions, and none need have occurred if the oils were of proper quality, *i.e.*, had a high flashing and burning point. We find from the report that the testers ordinarily used are quite variable in value, but the per cent. of actually dangerous oils in the market is not given.

The report upon butter and milk, by Drs. Chandler and Munsell, shows that among 40 samples of butter, over 16 were adulterated. Of 28 samples of lard, 10 had from 1 to 7.5 per cent. of water, and were more or less bad in quality.

Of 16 samples of olive oil, 9 were considered adulterated.

As regards milk, the old story of skimming and water-

ing is repeated. Among 73 so-called "creameries," 63 send skimmed milk to New York City, which is sold as pure milk. The condensed milk sold to New York customers was found to be unobjectionable, except that in a few instances the milk had been skimmed.

Professor Caldwell analyzed 29 samples of quinine pills, and found that in every case the quinine sulphate was below the amount claimed.

Professor A. H. Chester presents the analyses of nine samples of popular meat extracts. A few contained gelatine, but there was no other adulteration. Even in a peptone preparation, however, there was no soluble albumen, and in general the claims for the extracts are considered very much exaggerated.

In a report upon baker's chemicals, Dr. Love takes up the "alum question," and considers that at the present time there is not sufficient evidence of the injurious action of alum upon the animal system to warrant its prohibition.

Professor Labimore shows that out of 180 samples of spices, 112 were adulterated.

In a report upon drugs, Dr. Frederick Hoffman states that among 232 samples of crude vegetable drugs, 85 were adulterated or below the proper standard. Nearly one-half of the powdered drugs were not of the required purity or strength, and powdered drugs are considered to be of questionable reliability.

A DICTIONARY OF MEDICINE, INCLUDING GENERAL PATHOLOGY, GENERAL THERAPEUTICS, HYGIENE, AND DISEASES PECULIAR TO WOMEN AND CHILDREN. By various writers. Edited by RICHARD QUAIN, M.D., F.R.S. Fellow and late Senior Censor of the Royal College of Physicians; Member of the Senate of the University of London, etc. 8vo, pp. 1,816. New York: D. Appleton & Co. 1883.

In this large, double-columned, closely printed octavo volume, we have alphabetically arranged the various subjects connected with practical medicine, clearly, fully, and concisely discussed by a large corps of distinguished writers. Each contributor was invited to write upon such topics only as he was familiar with. The description of each subject includes an account of its etiology and anatomical characters; its symptoms, course, duration, and terminations; its diagnosis, prognosis, and lastly, its treatment. General pathology comprehends articles on the origin, characters, and nature of disease. General therapeutics includes articles on the several classes of remedies, their modes of action and methods of use. The articles on hygiene treat of the causes of disease and their prevention, also the agencies and laws affecting public health. The diseases peculiar to women and children receive the fullest practical consideration both in aggregate and detail. Not only is the work a Dictionary of Medicine in its fullest sense; but it is so encyclopædic in its scope that it may be considered a condensed review of the entire field of practical medicine. Each subject is marked up to date and contains in a nutshell the accumulated experience of the leading medical men of the day. As a volume for ready reference and careful study, it will be found of immense value to the general practitioner and student.

A SYSTEM OF HUMAN ANATOMY, INCLUDING ITS MEDICAL AND SURGICAL RELATIONS. By HARRISON ALLEN, M.D., Professor of Physiology in the University of Pennsylvania. Section III., Muscles and Fasciæ. Philadelphia: Henry C. Lea's Son & Co. 1883.

The third section of this admirable work, treating of the muscles and fasciæ, contains nearly two hundred quarto pages, with several page plates, besides illustrations in the text. The general design is consistently carried out by a description of the organs from a strictly anatomical standpoint, with such discussion of their relations and functions as are considered of practical interest. The author succeeds in infusing an individuality in his work

which gives it the highest value. As remarked in a previous review, he studies anatomy in a new way, by applying it in a striking and direct method to the actual wants of the student and practitioner. In perusing page after page, the reader cannot fail to be impressed with the profound knowledge of the subject possessed by the author. He succeeds in making each topic interesting by the manner in which he applies the facts presented; facts which, except for this application, might not be sufficiently impressed upon the mind. So much for the text. We regret to say that the illustrations, although much improved in character, will hardly realize reasonable expectations. With few exceptions, they partake of a coarseness of execution which does neither the author or artist much credit. In a work of this kind such a criticism should by no means obtain. Some of the drawings are lacking in accuracy, while others fail, in consequence of their heavy and sketchy shading, to bring out the due proportions of different parts. For instance, the latter point obtains more particularly in Plate XLV., representing the muscles of the neck. In Fig. 1 the larynx and trachea are much too large, as are also the first rib and clavicle. The first rib and clavicle in Plate XIV. are also nearly twice the size they should be. In Fig. 2, on Plate XLV., the constrictor muscles of the pharynx do not represent the requisite degrees of rotundity, and have curiously distorted relations with each other. The muscles of the forearm and hand, as well as those of the abdomen, are well drawn, as are also those representing the muscles on the inside of the jaw on Plate XLIV. It is to be regretted that the artist has such a predilection toward heavy shading, which appears to render necessary such coarse printing of the names of the muscles on their surfaces. If the outlines only of the muscles were shaded, the drawings would have a more artistic appearance and finer finish, the different layers would be more satisfactorily brought out, while at the same time the names of the organs could be clearly represented in finer and better type.

Army News.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from January 27, 1883, to February 3, 1883.

KILBOURNE, HENRY S., Captain and Assistant Surgeon. The leave of absence granted December 21, 1882, Department of Dakota, is extended two months. S. O. 24, par. 3, A. G. O., January 29, 1883.

THE PHILADELPHIA POLICLINIC AND COLLEGE FOR GRADUATES.—New York has been visited by so many Philadelphia physicians, anxious to see the working of our Post-graduate Medical College and our Polyclinic, that it is evident that a polyclinic endemic is imminent in the Quaker City. In a recent issue we mentioned the inauguration of such a movement. The departments have been assigned as follows: Operative Surgery and Clinical Surgery, R. J. Levis, Surgeon to the Pennsylvania Hospital; Diseases of the Throat and Nose, J. Solis Cohen, Professor of Laryngology in the Jefferson Medical College; Diseases of the Mind and Nervous System, Charles K. Mills, Lecturer on Nervous Diseases in the University of Pennsylvania; Orthopædic and General Surgery, Thos. G. Morton, Surgeon to the Orthopædic and to the Pennsylvania Hospitals; Diseases of the Eye, Geo. C. Harlan, Professor of Ophthalmology in the Jefferson Medical College; Diseases of the Ear, Charles H. Burnett, Aural Surgeon to the Presbyterian Hospital; Diseases of Women and Children, Edward L. Duer, Obstetrician to the Philadelphia Hospital; Pathology and Microscopy, E. O. Shakespeare, Pathologist to the Philadelphia Hospital; Applied Anatomy and Practical Surgery, John B. Roberts; Diseases of the Chest and General Medicine; James C. Wilson, Physician to the Philadelphia Hospital; Clinical Chemistry and Hygiene, Henry Leffmann, Demonstrator of Chemistry in the Pennsylvania College of Dental Surgery; Diseases of the Skin, Arthur Von Harlingen, Consulting Physician to the Philadelphia Dispensary for Skin Diseases.

The Secretary is Dr. J. B. Roberts, who is known to New York physicians, in connection with the Philadelphia School of Anatomy, and as editor of the last American edition of Bryant's "Surgery." Reference to the "Medical Register" of Philadelphia, shows that seven of the twelve professors are graduates of the University of Pennsylvania. The alumni of this time-honored institution, thus again prove themselves active promoters of advanced medical education. The fact of the two great Philadelphia Schools being almost equally represented in the new enterprise, is an auspicious omen for the future.

With one or two exceptions, all these men are known in medical literature. Good writers, however, do not always make good teachers. Some of them are among the younger members of the profession; but youth is not objectionable if united with energy and intellect. It will be interesting to watch the further development of this medical embryo of mixed parentage.

MILK AND TYPHOID FEVER.—An interesting case of the probable spread of typhoid fever, by milk contaminated by the use of impure well water for dairy purposes, is related in a report quoted in the *Lancet*. Twenty-one persons in sixteen households in Clapham, England, were affected. The houses were of the superior class and widely separated. Investigation exhibited no one sanitary condition as a cause common to the households affected, but suspicion attached to the supply of one milk dealer who obtained a part of his milk from two dairy farms at Musbury, near Axminster. His customers were divided into those who took "nursery" milk alone, nursery and ordinary milk, and ordinary milk alone. The enteric fever was found to be entirely limited to the consumers of the ordinary milk, one in seven of every house so supplied being affected. Several of the large houses taking large supplies were affected with the disease. The ordinary milk was supplied from the two farms referred to, and these were at once inspected. Neither of them exhibited the sanitary conditions which should exist on a dairy farm. At one the water was derived from a well sunk in a gravelly soil, and was shown on analysis by Dr. Dupré to be largely polluted by sewage or surface drainage, being entirely unfit for drinking or culinary purposes.

About eight yards from the dairy and twelve yards from the supposed position of the well belonging to it is a brook which higher up flows through a rough stone

sewer. Last winter six cases of enteric fever occurred in Musbury, the last one being still ill during the month of March; and it is known that the infectious excreta from this case were thrown into a privy with a vault of primitive construction, from which, when full, the contents are got rid of by pouring down water, and washing them away through a rough drain into the sewer. The persons affected with enteric fever were not specially exposed to any known local conditions likely to have brought about the disease; they were not in any close personal relation with each other, but they had a milk supply in common, and that this supply came from the dairy farm in question at Musbury, where there had been at no remote date enteric fever, with the possibility of access of the specific poison to the dairy farm well by percolation from the sewage-polluted brook through a porous, gravelly soil. These facts render it highly probable, if not practically certain, that the infection was distributed through the medium of the milk.—*Sanitary Engineer*, November 23, 1882.

CONCERNING THE DOSE OF ACONITE IN THE BRITISH PHARMACOPEIA.—Dr. W. M. Bracken, of Thompson, Conn., writes: "In your issue of January 13th, p. 56, Dr. Murrell is reported to have said, 'The dose of tincture of aconite recommended in the British Pharmacopœia—from five to fifteen minims—is absurdly large, and no one with any regard for his patient's safety or his own reputation would ever think of giving it.' The same statement will apply to the dose—one to five minims—generally recommended by American authors. A comparison gives the following: The B. P. formula has one part powdered root in eight parts of the tincture. The U. S. P. formula has one part powdered root in *two and a half* parts of the tincture. Dose, B. P., five to fifteen minims; dose, U. S. authorities, one to five minims—equal to three and a half, to sixteen and a half minims of the B. P. tincture. The U. S. minimum dose is less, but the maximum dose greater, therefore, than that which Dr. Murrell condemns. It is further recommended 'to put half a drachm of the tincture in a four-ounce bottle of water, and to tell the patient to take a teaspoonful of this every ten minutes for the first hour, and after this hourly for some hours.' This, of course, refers to the B. P. tincture. The U. S. P. equivalent would be *eight and a half minims*.

"The case of poisoning also reported in the same issue (p. 42, 'Directions Regarding Administration of Medicines') seems worthy of note. A physician directs two teaspoonfuls of chlorate of potash 'to be dissolved in a tumbler of water' (about six drachms by weight of the potash in six ounces of water), two teaspoonfuls of this solution to be used at intervals as a gargle. The patient, a girl aged fourteen, by mistake takes the two teaspoonfuls of the solution internally four times daily and develops symptoms of poisoning in less than thirty-six hours, death following. Supposing all the chlorate of potash to have been dissolved, the patient was taking fifteen grains four times a day. This would hardly be considered *poisonous*, the ordinary dose for an adult being from five to twenty grains. But it is not at all probable that the chlorate of potash was entirely dissolved, for this would have given one part in eight of the solution, while only one part of the chlorate is soluble in sixteen parts of cold water. A cold saturated solution, therefore, would have given but seven and a half grain-doses. We are glad to learn that the 'jury exonerated the physician!'"

THE MEDICAL STUDENTS OF SWITZERLAND.—There are in the four Universities of Switzerland—Basle, Berne, Geneva, and Zürich—a total of 543 medical students, of whom 51 are women. The largest class is at Zürich, where the number is 180. At Berne the number is 164. There are women medical students at all the universities except Basle. At Berne there are 26, at Zürich 17, and at Geneva 8.

ON THE SUCCESSFUL TREATMENT OF EXTRA-UTERINE PREGNANCY.¹

By A. D. ROCKWELL, A.M., M.D.,

NEW YORK.

ELECTRO THERAPEUTIST TO THE NEW YORK STATE WOMAN'S HOSPITAL, ETC.

IN the first case of extra-uterine pregnancy which it was my fortune to treat, I was asked by Dr. T. G. Thomas, one of the consulting physicians, whether it was possible to readily destroy the life of the fetus by the electric current. I replied that it could undoubtedly be done, but the important question, it seemed to me, was, whether it could be accomplished without injury to the mother. This question was answered in the affirmative by the results that followed. The case was one of tubo-interstitial pregnancy, at the third month, and terminated favorably by the expulsion of the fetus and placenta through the uterus. The history of this interesting and remarkable case was carefully written out by the attending physician, Dr. Charles McBurney, and published in the *New York Medical Journal*, vol. xxii., No. 3. At the same time Dr. Thomas wrote out an interesting description of the case accompanied by illustrative drawings, which he kindly placed at my disposal, and which can be found in my third edition of "Beard and Rockwell's Medical and Surgical Electricity," p. 606.

The second case upon which I operated was in the practice of Dr. C. E. Billington, the accuracy of whose diagnosis was again confirmed by Dr. Thomas. The result in this case was entirely successful.

The third case I treated for Dr. Bache Emmet, who had in consultation both Dr. T. Addis Emmet and Dr. T. G. Thomas. Dr. Emmet's account of the case, with its favorable termination, may be found in the *New York Medical Journal*.

In the fourth case I operated for Dr. Everett Herrick, the diagnosis being doubly confirmed by Drs. Thomas and Emmet. In this case again the fetus was effectually destroyed, followed by the prompt recovery of the mother.

At the last meeting of the American Gynecological Society of Boston, Dr. T. G. Thomas read an exhaustive paper upon the subject, giving the histories of some twenty cases of extra-uterine pregnancy that had fallen under his observation, together with an account of most of the cases to which I have just alluded, and in which electricity was so successfully used. In addition to these I have more recently seen and operated upon three other cases of like character that have never been reported, and which, if possible, even more strongly confirm the incalculable value of the treatment in these dangerous but somewhat rare abnormalities of pregnancy.

The fifth case, which I saw with Dr. N. S. Westcott, was of a most interesting and unusual character, from the fact that with a normal uterine pregnancy was associated what we have every reason to believe was a tubal or extra-uterine pregnancy. Dr. Westcott had previously called Dr. Thomas in consultation, and it was at his suggestion that electricity was used. The patient, a lady, aged about thirty, last menstruated August 6, 1882. Subsequently she complained of more or less

discomfort and pain, with tenderness in the region of both ovaries, but especially marked on the left side. On September 18th an internal examination was made, and by conjoined manipulation a small tumor was discovered, about the size of a pullet's egg. It was situated some two inches to the left of the median line, nearly on a level with the brim of the pelvis, and could be moved from Douglas' cul-de-sac toward the margin of the ribs. The tumor gradually increased until it was larger than a billiard-ball. There seemed to be no reasonable doubt as to its character, and on October 24th, the treatment by electricity was attempted.

The constant current was used, with one pole introduced to the mass through the vagina, and the other over the tumor externally and with rapid interruptions. The maximum of current strength employed was eighteen cells, or, to speak more accurately, as different apparatus vary much in electro-motive force, a power of twenty-four volts.

This operation was repeated on October 25th, 28th, and 30th, causing the tumor not only to perceptibly decrease in size, but to change its seat by an inch or so as well. Since the last treatment it has gradually grown smaller, until at the present date it can barely be detected. At the same time there is now developing in the uterus a six months' fetus.

The sixth case occurred in the person of a young unmarried woman, residing outside the city limits, and by special request, and for sufficient reasons, the name of the attending physician will not be mentioned. From him I obtained the following history: Two weeks previously he first saw the case professionally, and found that she was suffering much pain in the right side, together with irregular discharges of blood. The patient had confessed to the possibility of pregnancy, and examination elicited many of the objective and subjective signs of this condition. Nausea occurred every morning, and changes had taken place in the areola. Digital examination revealed the fact that the os uteri was little, if any, changed from its normal condition. By pressure over the right side it was possible to feel a certain hardness not present on the other side, but by conjoined manipulation, with one finger in the vagina, a distinct rounded mass could be felt.

Examination per rectum revealed its presence even more distinctly. If pregnancy existed—and of this there seemed to be no reasonable doubt—it had advanced nearly to the fourth month, and as the tumor was large, much larger than in the case just related, there was evidently no time to lose. I had brought with me a suitable apparatus, and immediately operated by introducing one pole into the rectum, and placing the other externally. On account of the great distention of the Fallopian tube, and the danger of rupture, we felt the necessity of exercising the utmost care, and consequently made use of the interruptions, with a current strength of but twelve cells, or about sixteen volts. The current would then be quickly increased without interruption and allowed for a moment to pass in a continuous stream. The treatment was concluded by a second application on the following day. Visiting the patient some two weeks subsequently, I found that the tumor had decreased in size at least one-half, and at this time, after the lapse of several months, it may be said, so far as any external evidence of it is concerned, to have entirely disappeared.

* ¹ Read before the Harlem Medical Association, February 8, 1883.

The last case is as follows: On December 14, 1882, I was informed by Dr. H. Marion Sims, that Mrs. A—, a patient of his, was suffering from extra-uterine pregnancy, and was by him requested to undertake the destruction of the foetus by electricity.

Although married a number of years, she had never before been pregnant. Dr. Sims, on first discovering the possibilities of this condition, called in consultation Dr. T. Addis Emmet, who positively confirmed the diagnosis. The pregnancy had advanced to the third month, and the tumor, which was about the size of a child's fist, was movable and could be distinctly felt both from without and within.

The size of the enlargement was such that the operation was urged immediately. For fear that the cyst might be in danger of rupture through uncontrollable movements of the patient, Dr. Emmet advised the administration of an anæsthetic.

Ether having been given by Dr. M. H. Nash, Dr. Sims placed the uterine electrode, and shocks from a galvanic current of but sixteen volts in strength were passed through the foetal mass.

The mildness of the treatment was necessitated because of the unusual nerve-irritability, and the violence of the muscular contractions.

Although it was probable that the destruction of the foetal life had been effected at the first séance, the operation was repeated on the 18th, 24th, and 27th of December, for the purpose, first, of absolute certainty, and second, to accelerate the absorptive process. The contour and seat of the tumor were not only changed after the first application, but it rapidly decreased in size. The patient experienced no unpleasant effects, and within a short time was able to start for Europe.

In the treatment of extra-uterine pregnancy, it is an important point to be decided, as to the best form of electricity to be used. Not only has galvanism and electro-magnetism been successfully employed, but it is said that the common magneto-electric battery has also proved sufficient, but from both a physical and physiological point of view, and as well through the teachings of experience, I cannot, for my part, doubt that galvanism is preferable to the other forms. It is more certain in its effects. It has a greater power of overcoming resistance, and consequently its influence is felt deeper than the other forms. Four important effects attend the passage of the electric current through the living body, and all these undoubtedly enter as factors, either in destroying the life of the foetus, or in the subsequent process of absorption.

These effects may be designated as mechanical, physical, chemical, and physiological.

The mechanical effects of the interrupted galvanic current are equal to those of the faradic current, while the physical effects, manifested by heat, and the modification of endosmose and exosmose are in the main the results of galvanic action.

By the passage of the galvanic current, the endosmotic phenomena may be both stimulated and reversed. The faradic current from the secondary coil produces no such effect. The current from the inner coil, produces these effects, but in a much less degree. Chemical or electrolytic effects, again, are almost wholly the result of galvanic action, and it should be remembered that the electrolysis of organic substances starts a process that continues long after the current ceases to flow. The physiological effects of electricity are those which take place by virtue of the vital properties of the body, and unlike the other effects, are only observed in living substances. Physiological effects are manifested on the circulation, on secretion and excretion, but only as absorption is effected does it interest us here, and it is quite evident that the absorptive powers of the secondary current are quite limited.

In any case of tubal pregnancy, and especially in those advanced conditions where the tube is greatly dis-

tended, and there is danger of spontaneous rupture, the possibility of hastening this catastrophe in the attempt to destroy the life of the foetus should never be lost sight of. The tubes themselves are but slightly supplied with muscular fibre, and the danger would more especially arise from the powerful compression that is liable to be exerted by the abdominal muscles, and the effort should be so to diffuse the current proceeding from the external pole, as to produce the least mechanical effect possible. In regard to the diagnosis of extra-uterine pregnancy, it must be confessed that it is not always an easy matter, and in the cases just related the question may arise as to its accuracy. The eminence of the gentlemen associated in the cases should perhaps be a sufficiently strong argument for the correctness of the diagnosis, but conclusive evidence lies also in the effects of the treatment itself. The results of the electrolysis are well known, but in no other form of tumor, cystic or otherwise, is it possible for the galvanic current, used as described, to produce similarly prompt and effective results. In regard to the effects of electricity on normal pregnancy, suggested by the case of double pregnancy that I have related, a word may be said. It is a mistake to suppose that abortions are readily produced by electricity. Without the electrode is introduced directly into the uterus, which would of course be sufficient without the passage of any current, the strongest treatment that it is prudent to give may prove insufficient. Of this I have had evidence in several justifiable attempts to bring on a miscarriage. In the case just alluded to the current was strong, applied by shocks, and in close proximity to the uterus, affecting it not only reflexly, but in some measure directly, yet the normal pregnancy was in no ways disturbed; and, so far as concerns general applications for the production of constitutional tonic effects, I have in many instances administered them with impunity through the whole course of gestation, and with the most happy results.

THE NEGATIVE PULSE OF THE VEINS.

No. 1.

No. 2.

It was obtained from a young woman, formerly active in habit, but who, without organic disease, had developed inability for physical work. She appeared incapable of effort, and would frequently remain all day in bed. She had become somewhat emaciated, but her appetite remained remarkably good, her digestion was perfect, and she slept well. She was always pale, and upon walking a short distance her lips would become almost white, yet she never experienced dyspnoea, her heart and her lungs were healthy, and her blood-corpuscles approached the normal in number and size. She complained of constant fatigue, and of a sensation of heat in her extremities, which was especially present at night. Upon one of these occasions the temperature of her hands was found to be 99° F., that of the mouth and of the hands being the same. The veins of the hands were prominent, and usually gorged with blood. This patient felt better in cold weather, and she derived benefit from sea-baths.

In the observation referred to, Ponce's sphygmograph was used. It was supposed to have been adjusted over the radial artery at the wrist.

The usual reactions of my experiment were an increased arterial blood-pressure, then a diminished arterial

¹ Cutaneous Irritation and the Pulse: New York MEDICAL RECORD, September 30, 1882.

blood-pressure and a slowed pulse, following the stimulation of the cutaneous nerves. The pulse of this patient was sometimes accelerated. In no other way was it affected by the irritation employed. The observations were therefore discontinued, and for several months the subject was dismissed from my mind.

Later, however, similar tracings were obtained from other cases, in which also the pulse was unaffected by the irritation. I therefore grew to associate their contrary character with a peculiar obstinacy toward the reactions named.

By closer observation in Case I., at the side of and external to the artery, a vein was discovered, which sometimes could be rolled under the finger, and frequently distinctly felt. The instrument was applied over this vein, and a tracing, which in every essential characteristic resembled Trace No. 1, was obtained.

In other cases, where the vein could not be felt, having recognized the arterial pulse, the instrument was moved slightly toward the external side of the arm. This manœuvre produced with many subjects an absolutely negative result. From a number, however, tracings similar to Trace No. 1 were obtained. In each of these instances the corresponding arterial trace registered a tension which was abnormally low. The heart was normal in each case.

With good arterial tension, by the readjustment of the instrument a line which resembled a line of respiratory variation was sometimes produced. This line did, in fact, correspond with the movements of the patient's chest, its convexity was formed during expiration, and its concavity during inspiration. This line was more frequently met than was that of pulsation. In one patient both were present, the base of the pulsation following the curve of the respiratory line.

The vessels of the forearm alone were subjected to observation. In Case I., however, a similar pulse was obtained also in a vein of the foot. Traces 3 to 6 were methodically taken from this case.

CASE I.—Arterial relaxation—heart normal.

No. 3.—Pressure 16; radial artery.

No. 4.—Pressure 6; radial vein.

No. 5.—Pressure 12; dorsalis pedis artery.

No. 6.—Pressure 4; dorsalis pedis vein.

Trace 3 from the radial artery, Trace 4 from its external vein, Trace 5 from the dorsalis pedis artery, and Trace 6 from its internal vein. I suppose one of the *venæ comites* always to have been employed.

I never obtained peripheral pulsation in a superficial vein. From this circumstance a transmitted arterial impulse was suggested to me.

Very early, therefore, in the course of my investigation,

with the finger upon the artery and the instrument upon the vein, their points of coincidence were marked. In each instance, as shown in Trace 2, the impact of the artery occupied in the tracing of the vein the time of its line of descent. The pulsation of the vein, therefore, did not depend upon the relative position of the arterial wall.

The remainder of these tracings were obtained from two patients, whose symptoms referred to the heart. Case II. possessed stenosis of the aortic valve, without altered area of the apex beat.

CASE II.—Stenosis of the aortic valves.

No. 7.—Pressure 16; carotid artery.

No. 8.—Pressure 16; internal jugular vein.

No. 9.—Pressure 4; external jugular vein.

No. 10.—Pressure 16; radial artery.

No. 11.—Pressure 6; radial vein.

Traces 7 to 11 represent the pulse of the carotid artery, of the internal jugular vein, of the external jugular vein, of the radial artery, and of the radial vein in this patient.

Case III. presented no lesion of the valves. Dr. A. L. Loomis kindly examined each of these patients. Tricuspid difficulty was eliminated in both. Trace 12 represents the pulse of the radial artery, and Trace 13 the pulse of the external jugular vein in Case III.

CASE III.—Irregularity and feebleness of the heart—no valvular disease.

No. 12.—Pressure 12; radial artery.

No. 13.—Pressure 4; external jugular vein.

I did not obtain a tracing from the radial vein of this patient, neither did I obtain one from the jugular vein, excepting when the contractions of the heart were more than usually strong. In the veins of the neck, pulsation was sometimes apparent to the eye. Visually its most marked characteristic was its descent. As Case III. once

said, its beat was inward, or toward the vertebral column. In these cases, also, the descent of the vein occupied the time of the arterial percussion stroke.

We have therefore presented in this brief report a pulse which falls while that of the artery rises, and which rises while that of the artery falls, which has been found in veins of the neck, of the forearm, and of the foot, and which has been associated with arterial relaxation, with stenosis of the aortic valves, and of irregularity with feebleness in the action of the heart.

The occurrence of venous pulsation is not infrequent. Reports of such occurrence have been made, notably by Marey,² of pulsation in a vein of the leg with a systolic regurgitant murmur in the heart; by Boyer,³ of pulsation in superficial veins; by Friedreich,⁴ of pulsation in the veins of the neck, in the thyroid, and in an external thoracic vein with stenosis of the mitral and of the tricuspid valves; by Parrot,⁵ of pulsation in superficial veins; of pulsation in the veins of the extremities by Ward,⁶ by Davis,⁷ and by Groves;⁸ by Benson,⁹ of pulsation in both upper extremities in a patient having mitral stenosis and tricuspid insufficiency with dilatation of the right heart; by Seidel,¹⁰ of pulsation in the jugular and in superficial veins; by Bamberger,¹¹ and by Geigel,¹² also a venous pulse with insufficiency of the tricuspid valve; by Collis and Groves,¹³ of venous pulsation in pneumonia; by Quincke,¹⁴ of pulsation in the veins of the forearm and hand in a case of cholelithiasis, also in a case of paraplegia from fracture of the spinal column at the level of the fourth cervical vertebra, and more recently by Dimer,¹⁵ of pulsation in the pulmonary veins and in the inferior vena cava after the opening of the thorax; by Gottwalt,¹⁶ of pulsation in the venæ cavae, in the veins of the neck, and in a brachial vein, and by Mosso,¹⁷ by Riegel,¹⁸ and by Franck,¹⁹ of pulsation in the veins of the neck.

Three varieties of venous pulsation have been recognized. The first variety consists of a regurgitant wave. It is due to insufficiency of the valves of the veins and of the auriculo-ventricular valve of the right side of the heart. By means of this insufficiency the ventricular systole causes not only a forward impulse to the blood in the pulmonary artery, but also a backward impulse to the blood in the auricle, the venæ cavae, the jugulars, and even in more peripheral veins. This variety was the earliest known. Formerly any venous pulsation was considered pathognomonic of regurgitation through the tricuspid valve. Friedreich²⁰ says: "It is unquestionable that without valvular insufficiency a venous pulse cannot exist."

In agreement with this opinion were Roncati,²¹ Thomm,²² Rosenstein,²³ Eichhorst,²⁴ Oppolzer,²⁵ Bamberger,²⁶ Geigel,²⁷ and Seidel.²⁸

The second variety of venous pulsation is due to relaxation of the minute arteries. It consists of a projection of the arterial wave.

In Bernard's experiment upon the submaxillary gland²⁹ by stimulation of the chorda tympani, or of the lingual below the emergence of that nerve, it is observed that the arterioles become dilated, pulsation appears in the capillaries, and the blood issues in jets from the veins. This occurrence is recognized by all physiologists. Flint³⁰ has called it the true venous pulse. Marey³¹ considers every peripheral venous pulse to be so produced.

Quincke³² in particular was assured of the centripetal character of his wave. He observed that the finger-tips paled and reddened with the contractions of the heart; also, that by compression of the brachial artery the pulsation could be made to cease, while with compression of the vein it ceased only on the proximal side. Low arterial tension was a prominent characteristic of Quincke's cases. Of the first he mentions that the pulse fell away quickly from the fingers, and of the second a paralysis of the vaso-motor nerves.

Pulsatory movement of the blood in the veins may occur, therefore, both from a centrifugal and from a centripetal impulse. In the latter instance the pulse is most marked at the periphery, in the former it is most marked near the heart. Both, however, are positively systolic. In both the wall of the vein rises at the same time as does the arterial wall.

The third variety of venous pulsation has been called the negative pulse of the vein.³³ It consists of an abrupt fall of pressure, which is synchronous with the contraction of the ventricle, and which is due to a periodic acceleration of the flow of blood into the heart. Modern interest in this pulse dates from the observations of Mosso.

Widemeyer,³⁴ however, in 1828, with one end of a glass tube immersed in water and the other end inserted into the jugular of a horse, noted pulsatory oscillations of the fluid in the tube.

Weyrich,³⁵ in 1845, repeated the experiment upon dogs. He found the fluid to rise during the systole and to fall during the diastole of the heart. The phenomenon was obtained, however, only in the vena cava and in the innominate vein. According to Rollett,³⁶ Weyrich attributed the ascent of the fluid to the aspiratory influence of the auricle at the moment of its relaxation. This theory is referred to also by Ludwig³⁷ and by Donders.³⁸ Mosso,³⁹ however, considered the negative pulse due to periodic acceleration of the venous flow from the increased thoracic aspiration which accompanies the systole of the heart.

That the heart occupies less space during its systole than during its diastole has been demonstrated by Marey,⁴⁰ by Mosso and Pagliani,⁴¹ and by François Franck.⁴²

The yet contracting amphibian heart was placed in water, having access to a tube through which its oscillations were measured. The fluid was found to rise during the systole and to fall during the diastole.

François Franck and Stefani⁴³ corroborated this result upon the living animal by means of a canula inserted into the pericardial sac.

Also Voit⁴⁴ obtained a similar result with an instrument for measuring aspiratory force. With the tube in the mouth during suspension of respiration, he observed the fluid to rise during the systole and to fall during the diastole of the heart.

Mosso's observations have attracted considerable remark, though physiologists have been, as a rule, conservative regarding the acceptance of his views.

Rollett,⁴⁵ however, credits Mosso with the recognition of a normal venous pulse.

Franz Riegel (*Berl. klin. Wochenschrift*, May 2, 1881) states that he has observed in dogs a venous pulse which alternated in time with that of the arteries. Also that in many healthy men he had obtained a pulse which did not differ from that which he had obtained in dogs. He sums up by saying there exists a normal venous pulse. This pulse falls during the heart's (ventricle's) systole and rises during its diastole. It is explained by the fact that during the systole of the heart (ventricle) the flow of blood from the veins is accelerated, while during the diastole of the heart it is retarded.

May 14, 1881, an article appeared by Gottwalt entitled "The Normal Venous Pulse" (*Pflüger's Archives*) Gottwalt's observations were upon dogs. His apparatus was somewhat unique. The vein was dissected from its surroundings. Under it was placed a concave tambour and above it a closely fitting metal plate. The conducting and registering apparatus were of the usual kind. Gottwalt's curve consisted of one large wave followed by two smaller ones. So nearly as he could judge, the second sound of the heart corresponded in time with the apex of the first smaller wave.

The efforts of this author, however, were principally directed toward determining the extent of the pulse. For this purpose other methods were more satisfactory than the use of the tambour. A small mirror was placed upon the vessel, and its reflection was noted upon the wall. Also the handle of a scalpel was placed under the vein, sufficient upward pressure being used to obliterate its lumen. If the pulse were present upon the proximal side of the scalpel, the blood might be seen to advance and to recede like waves upon the level shore of a summer sea. By this means he traced it in the inferior vena cava to the renal vein, in the internal jugular to the head, in the external jugular to the middle of the neck, and once in a vein of the arm.

Gottwalt says the respiratory undulations extend farther than do the pulsations. He detected respiratory movement in the femoral when pulsation was confined to the vena cava above the renal vein. He opposes Mosso's theory of causation, finding the pulse equally marked after the opening of the thorax.

In 1882 an article appeared by Riegel upon "The Normal and Pathological Venous Pulse" (*Deutsches Archives f. klin. Med.*, May 30, 1882), with simultaneous traces from the carotid artery and from the jugular vein. The normal pulse was found upon patients as follows:

CASE I.—Woman, thirty years of age; joint-affection; four months pregnant; thin, but has no disease of internal organs, nor of the circulatory apparatus.

CASE II.—Girl, eleven years of age; pale; has a large ovarian cyst; no lesion of the heart.

CASE III.—Young man; chronic nephritis; heart normal.

CASE IV.—Man, fifty-five years of age; somewhat enfeebled; having the appearance of commencing multiple sclerosis.

CASE V.—Man, thirty-five years of age; hæmatemesis; high grade of anemia.

CASE VI.—Boy, eleven years of age; convalescing from croupous pneumonia.

CASE VII.—Man, twenty-five years of age; convalescing from pneumonia.

CASE VIII.—Man, thirty-three years of age; chronic nephritis.

CASE IX.—Shoemaker; poorly nourished; signs of phthisis.

CASE X.—Girl, sixteen years of age; convalescing from pleurisy.

In the tracings obtained the time of the ascent from the artery occupied the time of the descent from the vein. The ascent was prolonged and dicrotic, while the descent was monocrotic and quick.

Riegel also gives simultaneous venous and arterial traces in stenosis of the mitral and insufficiency of the tricuspid valve. These traces did not differ in character from those obtained with the normal heart, but the percussion-wave from the artery here occupied the time of the second and greater wave from the vein.

Riegel concludes:

First.—In dogs there is a normal pulsatory movement in the jugular vein.

Second.—In many healthy men there can be found likewise a pulse in the jugular vein. It is probable that such a pulse always exists.

Third.—This pulse is not dependent upon a backward wave, but upon the alternate retardation and acceleration of the flow of blood into the heart.

Fourth.—The normal venous pulse falls synchronously with the heart's (ventricle's) systole, and rises with its diastole.

Fifth.—The normal venous pulse does not require any insufficiency in the valves of the veins.

Sixth.—Besides the normal venous pulse there is a systolic venous pulse observed in men, and principally in the jugular vein and in the liver.

Seventh.—This backward venous pulse can occur only from insufficiency of the tricuspid valve.

Eighth.—This pulse does not differ from the normal venous pulse in form, but in time, being systolic, while the other rises during the diastole of the heart.

Still more definite observations upon this subject were reported in April, 1882, by François Franck (*Gaz. Hebdomadaire de Med. et de Chir.*), who gives tracings taken simultaneously from the jugular vein and from the heart.

The tracing from the vein is similar in form to that given by Riegel. Following the sequence of the cardiogram, however, it is supposed to consist of, 1, a sudden rise and descent at the commencement of the total curve; 2, a second rise and descent; 3, a gradual ascent, and then again a sudden rise, indicating the commencement of a new series. The sudden rise and descent were synchronous with the contraction and relaxation of the auricle, and occurred with equal promptitude when the contractions of the ventricle were arrested by stimulation of the pneumogastric nerve. The second rise accompanied the ventricular systole.

His explanation is as follows: The sudden rise is due to increased pressure from obstructed flow at the instant of the contraction of the auricle and the sudden fall to rapidity of the current at the commencement of the diastole when the blood precipitates itself into the relaxing auricle. The second rise is due to retardation of the current from the loss of the aspiratory influence of the auricle and the second fall to a new acceleration from relaxation of the ventricle, while the gradual ascent is due to retardation from the gradual repletion of the whole right heart.

According to Franck's schematic representation his curve commences at a point midway between its apex and the base line. Riegel, on the other hand, considers his curve to extend between the points where it reaches that line independently of the cardiac cycle of events. Riegel, however, agrees with Franck, in finding his abrupt line of descent synchronous with the contraction of the ventricle, and therefore of commencing auricular diastole.

Gottwalt, also, by placing the second sound of the heart at the apex of the first smaller wave has determined the apex of his largest wave to exactly the same period in time as the other two. Because each has similarly located his abrupt line of descent, not different, but the same phenomenon is supposed to have been under the observation of all, their peculiarities of description being due to the varying point at which the curve was supposed to have commenced.

⁴⁵ Rollett: Hermann's Hdb. der Phys., IV., 1, 188.

My own tracings, also, on account of their systolic descent, must be considered as records of the same pulse which has been described by Mosso, by Gottwalt, by Riegel, and by Franck.

From the history of the subject it is apparent that I have first recognized this pulse in the forearm and in the foot. The observations of Mosso, of Riegel, and of Franck were limited to the veins of the neck, while Gottwalt, who investigated the extent of the wave, found it only once beyond the jugular veins, and then in a vein of the arm. All of these observations were conducted under conditions which the observers have called normal. My tracings were obtained only with the circumstance of arterial relaxation or of insufficiency in the heart.

Venous pulsation with effusion into the pericardial sac has been noted by Stokes, by Knoll,⁴⁵ and by Cohnheim.⁴⁷

Riegel, upon animals injected the pericardium, and with one monometer in the carotid of one side and a second in the jugular of the other, noted the changes which occurred. In the commencement of the experiment the pulse of the carotid was high and possessing arterial character, and the pulse of the jugular was low and small. As the injection proceeded that of the carotid fell, until it could no longer be perceived. At the same time the pulse of the jugular up to a certain point gradually increased in size, when it, too, commenced to fall, and finally ceased to exist.

Riegel's tracings of this venous pulse did not differ in character or time from those obtained with the normal heart. Franck⁴⁶ has determined that with pericardial compression the arterial pressure sinks, while that of the veins is increased. By arterial relaxation the same condition may be attained through increased swiftness of the arterial current, for while this swiftness is directly as the vigor of the heart, it is inversely as the peripheral resistance, which resistance is determined by the arterial tone.⁴⁹

The low arterial tension and the fulness of the veins in Case I. have been noted. The veins were prominent also in Case II.

This case presented aortic obstruction and regurgitation without alteration of the apex-beat. Niemeyer⁵⁰ notices that venous engorgement must result from a non-compensated valvular disease. In Case III. cyanosis was frequently marked. This case, however, only presented the venous pulse when the action of her heart was more than usually strong. Riegel's picture of the pulse of pericardial effusion is typical of my entire experience. With venous engorgement the negative pulse of the veins increases in size and extent until the advent of a pronounced failure in the heart, when it, too, tends to disappear with the disappearance of the arterial pulse.

To recapitulate:

First.—The negative pulse of the veins—called the diastolic venous pulse, called also the normal venous pulse—may occur in the forearm and foot.

Second.—This pulse contrasts with the arterial pulse not only in its negative character, in the slow ascent and quick descent of its curve, but also in the fact that its amplitude is increased with the increased fulness of the vessels in which it is found.

Third.—That it is therefore extended and accented by any cause which increases venous engorgement, whether it be arterial relaxation, obstruction in the lungs, insufficiency in the heart, or effusion into the pericardial sac.

The recognition of this pulse is important, because it may be of sufficient amplitude to mark the trace of the arterial pulse; because it must be eliminated in the diagnosis of the pulse of regurgitation through the tricuspid valve; and because it probably possesses a diagnostic importance of its own. With the Poud sphygmograph

its recognition in the forearm is not difficult. Having obtained the radial artery at the wrist, move the instrument $\frac{1}{2}$ to 1 c.m. toward the external side of the arm, remit one-half the pressure which had previously been employed, and if the pulse be present its tracing will appear.

113 EAST THIRTY-FIRST STREET,
January 23, 1883.

HINTS ON CASE-TAKING.

By J. WEST ROOSEVELT, M.D.,

NEW YORK.

This paper is intended to give an outline of the symptoms and signs to be sought for and recorded in medical cases. The importance of accuracy in recording cases is self-evident. The scheme here given may seem long and complicated, but in serious cases the facts sought may be all of importance. It will be seen that many of the questions refer to the possible existence of chronic disease of certain viscera. Information is sought in regard to such disease for various reasons, among which are the following: Prognosis in a given acute case may be gravely influenced by complicating chronic disease; differential diagnosis may be assisted by knowledge of such disease; an acute case may be followed by an outbreak of symptoms due to pre-existing chronic disease, which had heretofore remained in a comparatively quiescent condition, in which case knowledge that symptoms of such disease have previously existed is of interest and value. Moreover, autopsy frequently shows diseased conditions of certain organs which were never suspected during life. It is a matter of importance to know whether symptoms of such disease were ever manifest during life, or whether the conditions never gave any symptoms. It is often as necessary to state that symptoms do not exist as that they do.

The order in which the facts are recorded is, of course, not that in which they are obtained. It is suggested merely, because, if followed, it makes a connected history, with facts of a general nature as a sort of introduction. If the history of the case be covered by one of heads suggested in the scheme, it seems better so to change the order that such history fall just before the heading, "Present Condition." Common-sense must dictate how far the scheme shall be followed in each case.

In taking a history, the first points to be ascertained are the symptoms which trouble the patient most. He should, as far as possible, be made to tell his own story. Direct questions should be avoided until the physician is convinced that no more information can be obtained without them. The history should cover every point; but be as short as possible. Notes should be taken at the bedside, if practicable, in the form in which they are to be recorded, as this saves writing, and does away with the temptation to alter the record so as to fit the case, should it pursue an unexpected course. The physician should have no preconceived idea of how the case should run, but simply aim to record facts as they come to notice. Every sense should be trained, so that nothing escapes notice, and nothing is imagined to exist which does not exist. The previous history of a patient should be verified by judicious cross-examination. A history, when first recorded, had better be too long than too short. It may be shortened afterward, though the information contained in it should not be altered unless shown to be false.

GENERAL PLAN FOR THE RECORD.

Name of patient, age, civil condition, occupation, birth-place, race, residence.

These facts should head the history. The importance of recording the age of a patient is obvious. By civil condition is meant whether married, single, widow, or widower, facts which may or may not be important. Occupation, because of its bearing upon certain diseases

⁴⁵ Knoll: Ueber die Folgen der Herz-Compression.

⁴⁷ Cohnheim: Vorlesungen ueber Allg. Pathologie, Bd. I., S. 37.

⁴⁶ Franck: Trav. du Lab. de Marey, 1877.

⁴⁸ Rollett: Hermann's Hdb. der Phys., Bd. IV., Th. 1, S. 300.

⁵⁰ Niemeyer: Prac. Medicine, vol. II., p. 178. 1850.

should be noted. It is customary to note the birthplace, because information may thus be obtained leading to suspicion of diseases, endemic in certain localities, which may influence diagnosis. In this country, where so many races come under observation, information upon this point is interesting, because of the alleged different courses of various diseases in different races. Residence should be noted, because of its importance in infectious diseases, and in general hygienic conditions, favorable or unfavorable to disease.

FAMILY HISTORY.

Information should be obtained in regard to the existence or non-existence of the following diseases among near relatives (parents, grandparents, uncles, aunts, brothers, sisters, children):

Phthisis should be looked for. In connection with phthisis or tuberculosis, *struma* should be borne in mind.

Syphilis.—Unless the parents themselves can be observed, a history of syphilis in a family can rarely be obtained. When found, it is often of great value. Of course, this disease is of importance among relatives in a direct line with the patient, hardly so among collateral branches.

Gout, rheumatism, cardiac or renal disease, existing among relatives, may be of much interest and value.

Especially in the case of patients suffering from disease of the *nervous system*, similar disease among relatives should be noted.

Intemperance in many members of a patient's family should be recorded.

Tumors among relatives of patients, themselves suffering from tumor, is important.

Hæmophilia among relatives deserves investigation.

When any of the above diseases are shown with reasonable certainty to exist, it is sufficient to note the fact. When their existence seems only probable, the reasons for supposing them to exist should be stated.

The early history of the patient himself should now be recorded.

PREVIOUS HISTORY.

Use of stimulants.—Note if the patient drinks, how much, and what kind of liquor he uses. Cross-examination on this point is necessary. Before forming a judgment as to the temperance or intemperance of a patient, the number of glasses drunk daily should be ascertained. Also inquire whether the patient gets drunk, and if so, how frequently. Men who are not habitual drunkards rarely drink before breakfast, and the habit of drinking at this time almost necessarily shows that the patient drinks to excess. Information on this point may be valuable. There are patients who are evidently suffering from alcoholism who deny the use of liquor. Such must be judged upon their own merits. This subject is enlarged upon because of mankind's tendency to deceive in regard to the matter. Excessive use of tobacco may be noted.

Syphilis may be a factor in any case, no matter what the social or moral standing of the patient. Here, again, deliberate deception is not uncommon. Sometimes patients, especially women, do not seem to have noticed the primary sore. It will not do merely to ascertain the existence or non-existence of a chancre; the following symptoms should be looked for: If a sore be acknowledged, it should be ascertained how soon it appeared after a suspicious connection. Whether a sore be acknowledged or not, symptoms of constitutional infection may be discovered. Eruptions, falling off of the hair, sore throat, sore eyes, nocturnal headache, or other pains, tenderness of tibiae, sternum, clavicles, enlarged glands, gummy tumors, staining of the skin, ulcers—these are symptoms individually of more or less value, a history of which may be obtained from patients who deny all primary infection. The diagnosis of syphilis may be safely made if a number of them be admitted. The nature of the primary sore should be inquired into, and whether it was followed by

a suppurating or non-suppurating bubo. In infants the special symptoms of inherited syphilis must be looked for.

Rheumatism.—Attacks of acute inflammatory rheumatism, because of their relation to cardiac disease, and of the predisposition of patients having had one attack to others, must be noted. If a patient suffer from chronic arthritis, whether due apparently to rheumatism or not, it is as well to record the fact. So-called muscular rheumatism may be noted. Chorea should be noted for the same reason as rheumatism.

Scarlatina, being frequently followed by rheumatism, should be inquired into. The rheumatic attack in very young children may show itself only by tenderness of the joints without swelling or redness. The child seems to suffer pain and is restless, but only upon touching one of the affected joints can the cause of these symptoms be appreciated. It is very easy, therefore, to overlook the disease if the patient be too young to speak. Yet a rheumatic attack of this obscure nature may induce serious cardiac lesions.

Gout.—This disease should be differentiated from rheumatism, with which it is frequently confounded by the laity. The train of evils which gouty poisoning is stated by various authorities, with more or less show of reason, to induce, make an investigation of the subject necessary. It is stated to be an etiological factor in forms of renal and cardiac disease, skin diseases, dyspepsia, diabetes mellitus, asthma, bronchitis, neuralgia, especially of the fifth pair of nerves and sciatics, renal colic, and various affections of the central nervous system, besides a number of other diseases. Whether these statements are correct or not, should be determined, at least so far as certain diseases are concerned, by farther study.

The pains of syphilis or neuralgia may be mistaken by a patient for attacks of rheumatism or gout.

Malarial fevers.—In this country, where diseases of this type are so common, attacks of intermittent or other true malarial fevers should be noted. Poisoning from these diseases seems sometimes to leave its mark upon the constitution for a long time. It is to be remembered that typhoid and other continued fevers may be spoken of by the patient as "malarial." Hectic from any cause may be mistaken for intermittent. In cases where the patient states that he has had "chills and fever," he must be made to describe the disease.

Severe attacks of *any acute diseases* should be noted, and any *injury* which the patient may have received should be described.

Pulmonary disease, chronic in its nature, should be looked for. Cough and its character, expectoration and its nature, shortness of breath, fever, night-sweats, progressive loss of flesh and strength, hæmoptysis, any such symptoms are important, even if they have ceased to exist for some time before the patient comes under observation.

Cardiac disease, renal disease, dyspepsia.—These three classes of diseases are grouped together because some of their symptoms are so similar that it is impossible to separate them for purposes of general investigation. Palpitation of the heart, attacks of dyspnoea, and the effect of exertion upon those conditions; præcordial pain and anxiety, anginal attacks, or true angina pectoris; dimness of vision, seeing of floating spots (*muscae volitantes*); headache, local or general, sense of discomfort in head, mental depression, confusion of mind; lumbar pains; cedema of face or extremities, or any form of dropsy; changes in color or amount of urine (frequency of micturition may be mistaken for increased amount of urine); nausea and vomiting, abdominal pain or discomfort, flatulence, eructations, bitter or sour in taste, and the relation of these symptoms to the kind of food and the time it is taken; variations in the appetite, constipation or diarrhoea; these are the principal symptoms to be sought for in ordinary cases. Attacks of *jaundice* should be noted. The

presence of *hemorrhoids*, or the *passage of blood* at stool, may serve to direct attention to obstructed portal circulation.

Symptoms of disease of the *nervous system*, epileptiform seizures, paræsthesiæ, paralysis, neuralgia, and other pains, whether apparently of central origin or not, mental symptoms, hysterical symptoms, etc., are frequently important.

In men *sexual habits* should be investigated.

In women the history of the *menstrual life* should be taken. The time of the establishment of the function, irregularity of menstruation, menorrhagia, metrorrhagia, suppression of discharge, painful menstruation, leucorrhœa, pain in the back, headache, should be noted. Pregnancies, and their results in miscarriage or labor may be important. There are a certain number of cases in which sexual habits should be looked into. Hysteria in men or women must be remembered.

The *place of residence* of the patient, its sanitary condition as regards light, ventilation, cleanliness, warmth, drainage, and number of residents, is highly important in many cases. In *infectious disease* every possible source of contagion by fomites or otherwise should be sought.

After these facts should follow a clear account of the attack for which the patient seeks advice. The exact time when the attack commenced should, if possible, be ascertained; its mode of invasion, the order of development of symptoms, the possible causes (exposure to cold or infection, extraordinary exertion, a spree, anything which may be a factor in the case) should be carefully noted. Every detail which the patient is able to give in regard to his case should be recorded.

PRESENT CONDITION.

Under this heading it is intended to record the condition of a patient when he first comes under observation. The *general muscular development* of a patient and the quantity of adipose enveloped and his condition as to strength or weakness, being general notes, form properly the first observations to be recorded. The points next to be noted are the expression of the face, decubitus if the patient be in bed, peculiarities of gait or attitude if he be up. The color of hair, eyes, etc., may or may not be important. It is important to observe whether the face is pale, flushed, or normal in color. If pale, the skin may be translucent or opaque, very white, or yellowish or dirty white, or greenish; the lips and mucous membranes may be pallid, or bluish, or normal, or too red, and any of these conditions may be moderately or extremely marked—facts which should be recorded. If flushed, the redness may be bright or dusky, diffuse or localized, with the rest of the face pale or natural in color. The surface may be cyanosed. The color of the sclera may be white and natural, or yellowish or quite yellow, or bluish. It may appear opaque or translucent. The conjunctivæ may be injected or not. There may be lachrymation, or discharge of mucus from the eyes. There may be strabismus—a symptom of little value unless its existence or non-existence before the attack for which the patient seeks relief be ascertained. There may be nystagmus. The condition of the pupils, their size and reaction should be noted. They may be unequal or equal, both may react badly or well, or not at all, they may be dilated or contracted, one may react and the other not. One pupil may be irregular in outline, and this may be due to an old iritis, possibly, in its turn, due to past syphilitic or rheumatic outbreaks. In testing the pupils it is necessary to observe all the precautions usually advised. The eyes may be protuberant or sunken. The alæ of the nose may both dilate extremely with inspiration, or one may do so, or their movements may be hardly noticeable, or one or both may have a tendency to fall in with inspiration. The lips may be tremulous, pale, or red, or bluish, or purplish, dry or moist, cracked, or coated with sordes. The facial muscles may be almost immovable, giving the face

a vacant expression, or they may twitch, or they may be contracted, producing any variety of expression. The muscles upon one side of the face may be paralyzed, and on the other not; in muscular twitchings of the face any muscle or group of muscles may be affected. The tongue, its size, color, and coat, if present, must be described. The condition of the pharynx, tonsils, and interior of buccal cavity should be observed. Visible small veins should be noted when they occur in the face. They may be generally distributed over the face, or localized, as on the nose. The condition of the larger veins of the head and neck, as to fulness or emptiness, is important.

When possible, the entire body of a patient should be examined. The color of the skin, its temperature as appreciated by the hand, its moisture, its reaction to irritation, as shown by the redness which follows friction, the presence of the *tâche cerebrale*, the condition of the circulation as shown by the rapidity of the return of a normal color after pressure has whitened it, are points to be noted. Scars or ulcers should be described and their causes sought. Eruptions should be described in detail, and not merely mentioned by name. The condition of the extremities, in regard to warmth or coldness, and the condition of the circulation in them, clubbing of the fingers, whether the clubbing seems due to an increase of the size of the finger-end, or to wasting of tissue in this part, and consequent curving of the finger-nails, should be recorded. (Edema must be looked for. Enlarged cervical, epitrochlear, inguinal, or other lymphatic glands must be observed. When a gland is enlarged it should be stated whether it is hard or soft to the touch, painful or not.

The frequency of the *pulse* should be noted, and its character described. Some confusion has arisen in descriptions of the pulse owing to the loose way in which terms are used. Walshe, in his work on "Diseases of the Heart," gives the following classification of terms: "Each individual beat may be: 1, quick or slow; 2, short or long; 3, soft or hard, compressible or incompressible; 4, loose or tense; 5, empty or full; 6, narrow or broad, small or large; 7, single, double, treble, or multiple; 8, with or without special character, vibrating, jerking, bounding, undulating, wiry, filiform. In a series of beats the movements may be, 9, frequent or infrequent; 10, equal or unequal in force; 11, rhythmically regular or irregular." These terms are perfectly easy to comprehend, and as accuracy is important it is better to use them in the sense in which they were originally intended. The terms "quick" and "slow" must not be confounded with "frequent" and "infrequent," and due weight should be given to the terms describing the special character of the pulse. The sphygmograph, in the hands of one accustomed to its use, is a valuable means of recording certain conditions; but the tracings to be of value must be taken by one familiar with the instrument and its applications. The condition of the superficial arteries must be observed. They may be tortuous; their walls may be thickened; calcareous plates may be discovered in the wall; they may visibly pulsate. Pulsation in a vein will, of course, be noted. Influence of posture on the pulse is sometimes important.

The *respiration* should be observed, and its frequency and special character, if peculiar, noted. It may be shallow or deep, almost entirely abdominal or thoracic, labored or quiet. The rhythm may be regular or irregular, or of that peculiar type the "Cheyne-Stokes." When the respiration is labored it should be noted whether the intercostal spaces and supra-sternal notch, and supra and infra-clavicular regions collapse in a marked degree with the inspiratory effort, and also to what degree the accessory muscles of respiration are thrown into play. It is needless to say that thoracic respiration is the characteristic type with the female after puberty, and abdominal with the male and in children, and that a departure from this rule is abnormal. The respiration may be obstructed

by some abnormal condition in the larynx, in which case it may be accompanied by noises produced in this organ. There may be obstruction in the pharynx or nares, or buccal cavity. There may be stertor, due to paralysis from some cause of the *velum pendulum palati*; there may be dyspnoea, subjective, that is appreciated by the patient, or objective, that is appreciable to the observer. The effect of posture and exertion upon this dyspnoea are important points.

The *temperature* should in all cases be taken and recorded for a sufficient length of time to exclude fever. The frequency of the observation must vary in different cases. In continued fever of any type observations should be taken at least twice daily of the temperature, the frequency of the pulse and respiration being recorded at the same time. In severe cases the record should be made as frequently as may seem needful. The thermometer may be placed in the axilla, rectum, vagina, or mouth. The difference in heat between the axilla and the rectum or vagina is generally stated to be about one degree. It varies, however, in different cases. Whenever temperature records are made the situation in which the thermometer is placed should be noted.

The condition of the *bowels* and the appearance of the *stools* are important. Notes should also be made of the *appetite*, and any abnormalities of it.

The *urine* should be examined in every case. Albumen and sugar are the most important substances usually sought, and bile or bile-pigment. The reaction, specific gravity, and presence or absence of abnormal constituents should always be noted. It is better, in every case, as a matter of routine, to examine the urine by Fehling's test for sugar, no matter how low the specific gravity, for low specific gravity does not exclude this substance. In looking for albumen, the nitric acid test, applied according to the directions of Roberts, seems the best. The test-tube containing the urine is held at an angle of about 45° with the horizon, and a small amount of concentrated pure nitric acid allowed to trickle down the side. Being heavier than urine, it sinks to the bottom, and if albumen is present, even in very small amount, a cloud will form just over the surface of the acid. If this cloud disappears on heating the fluid, it is a precipitate of urates, if not, it is albumen. The quantity of acid used should not exceed one-tenth of the bulk of the urine. Heat should always be applied, as a proof that the cloud is albumen and not urates. It is well to boil some of the urine, and if a cloud forms to add a little acetic or nitric acid, when, if the cloud dissolves, it is composed of the phosphates; if not, it is albumen. The nitric acid test, as applied above, is, for clinical purposes, the most delicate yet proposed. A rough estimate of the amount of albumen present may be made by acidulating the urine, boiling, setting aside in a cool place, and after some hours estimating the proportion of the precipitate to the whole amount of fluid in the tube. The amount may be expressed in fractions. In collecting urine for examination, only perfectly clean vessels should be used, and it should be kept in a cool place, otherwise fermentation takes place rapidly. When observations are made upon the specific gravity, a specimen should be taken from the mixed urine passed in twenty-four hours, in order to obtain an average. It would be well, if possible, to estimate the amount of urea present in the urine. As far as I can discover there is no way of accurately ascertaining the amount of urea present, which is safe for any one but a chemist to use. The margin of error in every method which I have yet tried is, in the hands of one unaccustomed to chemical manipulations, very great. In all cases in which albumen is present, and in all cases where, from suspicion of renal disease or other reasons, it seems advisable, a microscopic examination should be made. The frequency of the chemical and microscopic examinations must vary in different cases. Once a week, in cases of albuminuria or glycosuria, seems the mini-

imum. As cases increase in severity the examination may be made more frequently. Some cases require a daily record of the amount of urine passed.

When necessary, the *reflexes* of skin and tendons should be examined, and areas of anaesthesia and hyperaesthesia, or other peculiarities of sensation sought for and described.

After these facts have been noted in every case, there should follow, as nearly as possible, in his own words, the symptoms of which the patient complains at the time he comes under observation. This is highly important. It gives clearness to the record, and brings into prominence symptoms which annoy the patient most. Every symptom should be described in detail.

Physical examination.—Although many of the signs to be recorded under the former heading are noted in a physical examination in its broader sense, yet it seems well to record in a separate paragraph the results of physical examination of the thorax and abdomen, and of any tumors which may be found. There is little to be said upon this subject, except that physical signs should be recorded in detail. Murmurs should be located accurately, their time, and areas of transmission, and intensity described. Abnormal signs in the lungs or pleurae should also be located. The size of the liver and spleen should be ascertained as far as possible. The condition of the abdomen as to distention from gas or fluid, the presence of pain or gurgling on pressure, and the location of such pain or gurgling must be noted.

FURTHER RECORD OF THE CASE.

The subsequent history of the case and its treatment must be noted as frequently as may seem advisable. All subsequent physical examinations should be recorded when made. It is better to have too many notes than too few.

A few more suggestions may be of value. It is important that a more detailed description of certain phenomena of disease be given than is usually the case. If a patient have a convulsive seizure, it should be noted whether he lose consciousness, whether the convulsion is local or general, tonic or clonic, or one form alternating with the other; whether the tongue is bitten; whether there is frothing at the mouth, flushing or pallor of the face, how the respiration and pulse are affected; whether there is a flow of urine soon after the fit, how severe the seizure is, what the condition of the pupils and eyes, the expression of the face. If there is an aura, it should be described. Any circumstance which may seem to have determined the seizure should be recorded.

Cases of unconsciousness call for most careful observation. Such information as may be derived from friends will be recorded. The age should be noted when it can be ascertained. When accurate information cannot be obtained, some conclusion in regard to age must be drawn from the patient's appearance. The muscular development and adipose envelope should be observed. It should be noted whether the insensibility is complete, or whether the patient can be roused in any way. The odor of the body and breath, condition of the mouth and tongue, frequency and character of the pulse and respiration, temperature, presence or absence of vomited matter, and character, if present; presence or absence of faeces or urine upon clothing are matters of importance. Oedema must be looked for. The color of the face and body, condition of circulation in extremities. Condition of the walls of the arteries as evidenced by touch. Condition of heart as evidenced by physical examination. Examination of lungs should be made. Condition of abdomen should be noted. If the coma be not so deep as to mask them, signs of paralysis may be found. Wounds or bruises must be described. The condition of the pupils and position of the eyes should be observed. Signs of tenderness in any part of the body are important. The urine should be drawn and examined, and its amount noted.

If many of the suggestions in this article are trite, it must be remembered that nothing original is claimed. If it arouses public attention to the necessity of more accuracy in the record of medical cases, it will have served its purpose. If it is dogmatic in style, it is because of the amount of compression necessary to condense the facts within the limits of a journal article.

THE IMPORTANCE OF A KNOWLEDGE OF THE RADICAL DIVERSITIES IN THE HUMAN RACE TO THE PHYSICIAN AND SURGEON.

By HARVEY L. BYRD, M.D.,

PRESIDENT, AND PROFESSOR OF OBSTETRICS AND DISEASES OF WOMEN AND CHILDREN IN BALTIMORE MEDICAL COLLEGE, BALTIMORE, MD.

WERE the science of ethnography more generally cultivated by practitioners of medicine than it is, and the great importance of race distinction and peculiarities better understood by physicians in their relations as cause and effect in certain epidemics and individual diseases also than at present, far less difficulty would be experienced in arriving at important information concerning the etiology and the therapeutics of many cases occurring in communities composed of diverse races, and of the hybrids frequently resulting from the intermingling or interbreeding of such races. While age, sex, idiosyncrasy, hereditary tendency, occupation, and habits of life, etc., are pretty generally discussed by professors in medical colleges and in the text-books in their relations to diseases, very little notice is taken, if any at all, of the great and radical distinctions and peculiarities which exist between the primordial types of mankind in their impressions upon, and in not a few instances their marked and unmistakable effects in the development and influence in diseases. These facts are well known to many intelligent practitioners in the Southern States of this country, whose experience extends back to ante-bellum times, and they always recognize their existence as factors of the greatest value in the treatment of their patients. Their importance can indeed hardly be overestimated by the judicious physician in many communities in which considerable numbers of the Caucasian and negro races exist. When they have been thoroughly studied and their value duly appreciated, I have no hesitancy in saying that they will be carefully regarded ever afterward, and their mandates promptly obeyed in the treatment of cases by all such practitioners as are at all ambitious of attaining a high standard of excellence and success in their profession. It is hardly necessary to mention the fact, in this connection, that there are anatomical and physiological differences and distinctions, of a conspicuous and permanent character, existing *now* between the three more prominent varieties of mankind, viz.: the Caucasian, Mongol, and Negro races, and there is every necessary reason for believing that they were stamped thus *ab initio* by the fiat of the Creative Will. The anatomical characteristics have not been lost in the osteological framework, at all events during the geological, monumental, and historic periods, and if certain Hebrew words or expressions admit of the interpretation that will be given to them further on in this paper, there can be no doubt of a diversity of creation and thus plurality of origin of the races of men; and hence those anatomical distinctions have continued commensurate with the being of the races upon the earth.

Parity in the general form and features is not greater among the races than are some of the symptoms in the diseases to which they are subject in common; but there are certain other symptoms that are more widely separated than even the color, and other anatomical peculiarities of face and form, in the three primordial types alluded to above. It does not appear necessary to introduce them here in support of our position, nor to present irrefutable evidence of the non-liability of some of those

races to certain diseases, *cæteris paribus*, to which the others are exposed, in order to show that nature has stamped in permanent living characters, in the phenomena to be seen at the bedside, laws that were ordained when they came into being for their governance throughout the ages. And thus we see the reason why the primordial races may be easily differentiated etiologically as well as ethnologically. Such being the case, it will be clearly obvious to those accustomed to interpret natural phenomena and law, that the highest degree of skill and success in the practice of our profession will not be attained by physicians generally until the professors and writers in all the *practical* departments of our science shall give due and proper weight and consideration to the laws ordained "in the beginning" for the control of those races, and that of the amalgamations that so often occur when they are intimately associated or brought into juxtaposition for any considerable period of time. And probably nowhere else in the vast expanse of the created universe, as far as we are permitted to know anything at present, can the operation of fundamental law be more clearly seen and easily appreciated by the thinking mind than in the structure, functions, and pathological characteristics that so conspicuously mark and distinguish the *hybrid offspring* of the Caucasian and Negro races when it is found breeding *intense*.

Properly directed and intelligent investigation and study of the mulatto in his individuality as a hybrid, and in his relations to the races from whom he sprang, at the present time, would render important service to the theologian as well as the physician, and also to the educated portion of mankind generally. It must be evident to the careful observer of events, that the enthusiasm which amounted to a furor almost on the advent of the Darwinian hypothesis, a few years ago, and which so violently assailed some of the old systems of theology as to shake them to their very foundations, and to threaten the overthrow, if not the utter annihilation of the less stable ones, is now gradually yielding to the pressure of new and important facts and to a better system of inductive reasoning, and no "missing links" are found necessary to show that the races of men are *now* what they were when they came into being under the fiat of the Creative Will. It appears, indeed, that, if a few Hebrew words are correctly translated, theology and ethnology (the written and the scientific teaching on the origin of the races constituting the genus homo), are in full and perfect harmony with each other, and establishes the further fact that all knowledge and "all (science) are but parts of one stupendous whole."

The axiom that like produces like is too universally known and admitted as a fundamental law to require anything much further than mere mention of it here; so that any subversion of its operations now by merely human or other agencies, if such were possible, would soon convert the harmonious relations of the existing order of things into utter chaos or complete annihilation. According to this law of propagation and descent, the primordial types of mankind have certainly undergone no marked or essential changes in their physical characteristics since their original creation. Caucasian men do not beget negro children, and *vice versa*. It were therefore a physiological absurdity to suppose that the testes and ovaries of a single pair of either of those primordial races contained, *ab initio*, the germs of their own future progeny and those of the descendants the *two other* races at one and the same time, to say nothing of the physiological impossibility of *any* race having been born and perpetuated from two individuals only. Hence, according to the doctrine of "like," such theories or assertions do not rise to the level of absurdity even when philosophically contemplated for a single moment; and I would therefore respectfully invite the attention of the reader to some statements made by Prof. Joseph C. Richardson at a late meeting of the Philadelphia County Medical Society, as

published in the *Medical Times*, page 166, December 2, 1882, in confirmation of my assertion. They are as follows, viz.: Dr. Richardson said "If you took the spermatozooids of an African, a Malay, an Indian, and a Caucasian—notwithstanding they were exactly alike morphologically, chemically, and in their reaction with staining fluids—and introduce them into suitable culture apparatus, you would find them, after a suitable number of months, so developed that they differed from one another *as much* as black does from white." This is the teaching of science, and not conjecture or hypothesis! Was it not always true? Hence I feel sure that few subjects of deeper interest or greater importance could well be brought before the thinkers in our profession, whether they should be of the Christian faith or Jewish belief, or of those inclined to the hypothesis of evolution, than this brief effort to prove from the Hebrew text that both the Bible and science teach the penal or diverse origin of the primordial types of the human race. And I therefore take the liberty to introduce a few Hebrew words and certain translations from the Sacred Volume to confirm what has been said above, so that the theologian as well as the physician, be he Christian or Jew, may readily join the rapidly advancing hosts of science, without the slightest apprehension that the truths of Revelation will sustain the smallest injury from the discoveries that are being almost daily made in the material world.

The Hebrew words alluded to above are *naphesh chayah*, which may and seemingly should be rendered "intellectual creatures with immortal souls," when we have only the words "living creatures," as in Genesis i., 24. If the word *naphesh* qualifies and invests *chayah*, the "living creatures," with "immortality and intellectuality," as it is thought to do, though it has not been translated in our present version of the Bible, it prepares the way for a clear and perfect understanding of what occurs in the twenty-sixth verse, where it is stated Elohim created *ha-Adam*, or "the Adamite." It appears that it was *Adam* that the Deity created in his image rather than "man," as rendered in the text. *Adam* and *ish* seem not to be convertible terms that may be translated alike, as the latter is always used, so we are informed by Hebrew scholars, when speaking of *man* and mankind generally. Thus: "And the Lord said, My spirit shall not always strive with *the Adamite* (*ha-Adam*), for *he also* is flesh." Not *ish*, or "man," as the former is translated in our present version of the Bible. It will be seen that the definite article is prefixed in the Hebrew. "And it repented the Lord that he had made *the Adamite*" (*ha-Adam*), not *ish*, or "man." "And the Lord said, I will destroy *the Adamite*," etc. "The sons of God" (evidently the sons of *Adam*, or *the Adamite*) (red men) and the *fair* "daughters of men" were manifestly of *different* races, and their intermarriage was a physiological necessity for the perpetuation of *the Adamite* race, as may be seen in Genesis vi., 2. And the *giants* alluded to in Genesis vi., 4, when speaking of the coming of "the sons of God" into "the daughters of men," were presumably, at least, of *another* and *entirely* distinct *race* from either of the other two just then spoken of.

It has been thought proper to introduce the foregoing testimony from the Bible for several reasons, but chiefly so for the following, viz.: 1st. As science and revelation are both of God, they must harmonize in the very nature of things; and, 2d, to establish as conclusively as facts are capable of doing, when applied by human intelligence and reason, the immutability of the laws of the Great Jehovah in their operation upon the human race; and, finally, to clear away, as far as may be, the mythical errors and hypothetical speculations which have so long environed the origin and subsequent intermingling of the types of the *genus homo*, so that perspicuous conceptions may be had concerning the physical, mental, and psychological character and characteristics of the races, in order that their mutual relations and their present dependence

upon one another may be better known and appreciated, both in health and in disease.

The paucity of our practical professional literature on this very important subject is such as scarcely to attract attention, and yet if we have succeeded in making our treatment of it at all well understood, even in its leading features, it will be seen that proportion, adaptation, and symmetry are the relations of the great facts we have been attempting to present, and that neither accident, nor chance, nor "natural selection" could have had any agency or control whatever in their original development. On a subsequent occasion some important facts in regard to the general effects of disease upon the varieties of mankind, and upon the human hybrids in particular, may claim attention in a brief journal article.

I would venture to state, in concluding the present paper, that I believe I can assert, without the fear of contradiction, or of satisfactory refutation at the least, that the Hebrew Bible positively and indubitably teaches that there were certainly *two* if not more *separate* and *distinct* creations of the human race, and that certain statements and logical influences, in particular narratives and allusions on many occasions, admit of a fair deduction that there were *several* if not many races or tribes that were contemporaneous with the Adamite race at its origin, and at other times, that were generally inimical to it and usually avoided consanguineous affiliations with it. All these facts will be readily elicited from our English version of the Bible by any one whose mind is free from early prejudice or training in regard to the teaching of the Sacred Volume. True science unquestionably declares a diversity of origin of the human race to the intelligent anatomist, physiologist, and physician. And thus the Bible and science are found to harmonize completely and perfectly in *all* that relates to the duty and obligation of the physician to his fellow-man in his moral, intellectual, and physical nature.

127 N. ARLINGTON AVENUE.

ADDISON'S DISEASE.—Semmola (*London Medical Record*, January 15, 1883), by new studies, confirms the opinion that Addison's disease must be considered an affection of the central nervous ganglia, and that the anatomical alterations of the suprarenal capsules are not the point of departure of the disease; but where they exist, they represent trophic disorders produced by the nervous filaments which preside over the nutrition of these organs, and this he demonstrated at the International Congress in London, with drawings which showed the microscopical alterations of some points of the central ganglia and of the dorsal section of the spinal cord, the alterations being a myxomatous transformation of the stroma of the coeliac axis, and leucocytic infiltration of the spinal medulla around the central canal.

He concludes that Addison's disease is a profound disorder of the renal nutrition, determined by the successive alteration of the functions of the sympathetic and of the different nervous centres of organic life (coeliac axis, etc.). And with the help of the physio-pathology of the central nervous ganglia, he explains all the successive symptoms of the malady, such as the disorders of digestion, the cachexia, the lowering of the temperature, etc. The discoloration of the skin, when no lesion of the suprarenal capsules can be found, may be attributed to the influence of the sympathetic and central nervous ganglia, which are certainly concerned in the formation of pigment. Not a few cases of melanodermy have occurred a few days after violent moral emotion.

Semmola confirms his assertion by quoting a case of Addison's disease, accompanied by syncope, in which the electrical current, passed from the neck to the epigastrium, did good. In other cases, with the same treatment, there were restoration of strength, increase of the temperature to the normal, improvement in digestion, and, above all, gradual disappearance of pigmentation.

Progress of Medical Science.

GOLTZ ON THE CORTEX CEREBR.—Professor Goltz, of Strasburg, has published a new series of experiments on the cerebral hemispheres of the dog, in which, instead of following his old method of destroying the cortex with a stream of water, he established the lesions by means of a White's boring machine. The general conclusions he arrives at are :—1. The hypothesis of circumscribed centres for special functions in the cerebral cortex is untenable. 2. There is no area of the cortex exclusively concerned with sight, hearing, smell, taste, or touch. 3. It is impossible by any circumscribed lesion of the cortex to produce permanent paralysis of any muscle, or remove it from the influence of the will. 4. The vital manifestations which we regard as indicative of intelligence, feeling, emotion, instinct, are not dependent on functionally differentiated cortical regions. 5. Destructive lesions of the frontal regions of the hemispheres cause defects which differ in certain respects from those caused by lesions of the occipital regions. These differences depend probably on simultaneous lesion of the conducting tracts which lead to the crura. So far as yet made out, the difference amounts only to this—that while removal of the anterior regions shows itself in clumsier movements and reduced tactile sensibility, removal of the hinder lobes more distinctly affects sight and other specialized senses. This concession to the localization hypothesis is guarded by a suggestion that the ground of the difference is to be sought for, not in the cortex itself, but in the underlying white tracts. The general intelligence is also somewhat more affected in destruction of the hinder lobes.—*American Journal of Insanity*.

ANTAGONISM BETWEEN VERATRIA AND POTASSIUM SALTS.—In some previous experiments Dr. Sidney Ringer found that circulating simple saline solution through the ventricle causes it after each contraction to dilate very slowly. In fact the trace is just like the trace of a ventricle poisoned by veratria. He showed also that a small dose of any potassium salt, 1 in 10,000 to 1 in 15,000 parts, will obviate this prolonged dilatation, making the ventricular dilatation normal. From numerous experiments more recently undertaken, Dr. Ringer concludes that a small dose of potassium chloride will completely obviate the effect of veratria, and restore normal cardiac contractions.—*The Practitioner*, January, 1883.

THE TREATMENT OF INTUSSUSCEPTION.—A prolonged and practical discussion on this subject was had at a recent meeting of the London Clinical Society (*British Medical Journal*, December 16, 1882).

The whole field of treatment was thoroughly gone over. And the points that should especially claim our attention throughout the course of such cases were brought out clearly and distinctly. There was a pleasant unanimity of opinion, more particularly as regarded surgical interference.

The general consensus of opinion pointed to the early treatment of all cases by inflation and operation. But it was also shown that a great distinction must be drawn between cases of simple intussusception, which may last for weeks when the bowel is not strangulated, and those of strangulated intussusception, in which any delay in operating is to be deprecated, since peritonitis is almost certain soon to ensue. The former cases are those most likely to be benefited by inflation and injection of liquid per anum, possibly the two combined, while the patient's abdomen is kept relaxed by the use of an anæsthetic. But if the strangulation has lasted for some time, and the symptoms are severe, so that there is reason to fear that adhesions may have formed, or the wall of the bowel have become softened by the inflammatory process, inflation or forcible enemata should scarcely then be attempted. Should the case be one of severity, and inflation be found valueless, the surgeon should at once have recourse to

abdominal section; just as in hernia, when taxis has failed, he directly proceeds to herniotomy.

The median line of the abdomen is to be chosen for incision, and the operation should be done with antiseptic precautions. The invaginated bowel may be either withdrawn by gentle traction from the encircling portion, or its withdrawal assisted by pushing up from below. Many speakers remarked upon the extreme difficulty they had sometimes experienced in returning the distended bowels into the peritoneal cavity after the operation, a difficulty which may be necessary to overcome by puncture of the intestine with a trocar and cannula, for the withdrawal of gas and liquid. But in cases in which the intussuscepted bowel cannot be withdrawn, what is to be done? As Dr. Buzzard pointed out, the portion of intestine inclosed goes on to slough and separation, and this is nature's method of cure in the very few cases which struggle on to recovery through the various dangers which beset the patient. Surgeons recommended that nature's method should be imitated, as nearly as may be, by a bold excision of all the implicated portion of bowel, and a stitching together of the two cut ends. Mr. Howse had already done this in two cases, though as yet without success. To avoid risk of the passage of any fecal material into the peritoneal cavity, he recommended that a thin sheet of gutta-percha material, with a slit in its centre, should be spread before the abdomen, and all the bowel to be operated upon drawn forward through the slit. It might then be treated without fear of fecal contamination of the peritoneum. It remains to be seen whether this bold procedure of excision will in future result in more success than has hitherto attended it. In certain cases, in which the bowel protrudes through the anus, Mr. Howse would also remove it bodily from that situation by amputation, securing the cut end by pins. An Italian surgeon has already done this by inadvertence, not knowing what he was taking away, and the patient recovered.

NEGLECTED MEASLES.—Dr. Danford Thomas, in his capacity as coroner, has directed public attention to the mortality which follows the neglect of measles. It is a common opinion among the poor that a child must have the measles, and that when it gets the disease it requires no treatment and but little care. This is a mistake. In the records of vital statistics it may be seen that it often proves more fatal in the large towns than any other zymotic disease, more even than scarlatina. With medical and parental care the disease generally does well. But without this it is liable to serious complications, and apt to leave disagreeable consequences.—*London Lancet*, December 23, 1882.

HEBEPHRENIA.—Dr. Fric, of Würzburg, considers that hebephrenia occupies in cerebromental pathology as legitimate a place as general paralysis. Its symptomatology is clear and well defined, and the prognosis can be established with certainty from the outset. This affection is tributary to psychic degeneration, by which is understood an early arrest of development of the brain, in virtue of which the intelligence does not attain its proper development, and at the period of puberty undergoes a regressive evolution. The truth of this statement can be deduced from the proteiform character of the delusions which occur, and from the incoherence of the ideas and acts, which are impulsive and instinctive—depression alternating with exaltation, and complete remissions unexpectedly supervening, followed by rapid relapses. Hebephrenia—and this has not escaped the notice of Morel—is a psychosis of degeneration, a congenital defect which remains latent during childhood and the early period of puberty, showing itself when the subjects are affected by the inexorable exigencies of life, or are called upon to make intellectual efforts of which they are incapable. Moral insanity cannot be mistaken for hebephrenia beyond its characteristic symptomatology; it remains stationary for a long series of years, while in hebephrenia

the intellectual loss is precocious. In hebephrenia the delusions are absurd and unreasonable, like those in general paralysis, and this character, which is an attribute of dementia, serves to distinguish them from systematized delusions. It is possible to confound hebephrenia with *folie circulaire*, such as has been described by Falret, but it is to be remarked that in *folie circulaire* the courses of mania and melancholia do not exclude a certain degree of lucidity which never occurs in hebephrenia, on account of the dementia; and the complete remissions observed in the latter never occur in the former. From the point of view of frequency, it can be affirmed—a neuropathic or psychopathic predisposition being admitted—that hebephrenia is that form of cerebro-mental disease which most frequently makes its appearance during adolescence. This fact is, however, only verified as regards men. Among females hysterical insanity is its equivalent. Katatonia and hebephrenia have so many points in common that it is often difficult, if not impossible, to distinguish them, for the spasmodic or cataleptic condition met with in the former is also often present in the latter, and one form may succeed another. In katatonia, however, recovery often ensues; hebephrenia, on the contrary, is absolutely incurable.—*Dublin Journal of Medical Science*, January, 1883.

THE TREATMENT OF DELIRIUM TREMENS.—In spite of all that has been written on this subject, Dr. Atkinson (*Practitioner*, January, 1883) thinks that sufficient attention is not given to the necessity of supplying the system with adequate nourishment. Certainly in the second stage, when the appetite is bad, the blood corpuscles deficient in quantity and shrivelled, and the brain anæmic and starved, it is useless to expect relief from sedatives unless the brain is at the same time supplied with the nourishment it requires. Death, no doubt, in delirium tremens arises from want of sleep, but then it must be remembered that the want of sleep is caused by want of nourishment. The most important part of the treatment then, is to improve the quality of the blood as quickly as possible by throwing into the system frequent supplies of light, nourishing, and easily digestible food. The best way of accomplishing this end is by cutting off all stimulants and ordering half a tin of Brand's liquid essence of beef, and half a pint of milk to be taken alternately every two hours. As regards medicine, twenty-five grains of chloral with thirty minims of compound tincture of cardamoms in an ounce of water taken every four hours, after the beef-tea, will be found most useful. Very little effect, though, is produced by the first dose of the chloral, inasmuch as the brain is without the nourishment it requires, but after the second dose the food begins to tell—some sleep, generally speaking, results, and this goes on increasing in proportion as the support is maintained. If nourishment is withheld, sleep disappears, and the old delirium returns.

By this treatment the patient is generally free from all delusions in about thirty-six hours, but good strong liquid food must still be taken for some days, though not quite so frequently. When there have been from ten to twelve hours more or less continuous sleep, then it is advisable to give up the chloral, and give thirty minims of the compound tincture of gentian with five minims of the tincture of nuxvomica three times a day for about three days. This restores the tone of the nervous system and stomach, and creates an appetite. A little tincture of euonymin may next be substituted for the nuxvomica, and some Carlsbad salt may be given in the morning when required. By this treatment the duration of the delirium and the after-effects of the alcohol are very much lessened.

RESECTION OF THE LUNG.—A medical man, practising in Dantzic, recently undertook the resection of the lung of a young female patient, with the consent of her parents. Through the denunciation of two colleagues, the case, which ended fatally, will be made the subject of judicial

inquiry. All parties, however, appear to admit that the attempt of the surgeon was made in perfect good faith, and in the full belief that it gave the patient a chance of recovery from an otherwise incurable disease. Was the surgeon's conduct simply foolhardy and entirely reprehensible, or was he, on the other hand, before his time? It is by no means impossible, judging from analogies that abound in scientific literature and biography, that works may appear, one century hence, treating of resection of the entire lung as a recognized operation, and recording how, in the nineteenth century, the first pneumotomist got into trouble. Some, though not the majority of innovators, live to see their views and their practices established.—*British Medical Journal*, December 30, 1882.

POISONING FROM SWALLOWING CHLOROFORM.—Oliver relates the case of a weakly man who swallowed over three ounces of chloroform. He was brought to the hospital at 11 P.M. The respiration was almost imperceptible, pulse very slow (twenty to the minute), feeble, and scarcely to be felt, skin cold and pale, face livid, pupils widely dilated, patient sleepy and anæsthetic. The breath smelt slightly of chloroform. Artificial respiration was at once begun. One pole of an induction-coil was placed over the heart, the other on the nape of the neck. Enemata of beef-tea with brandy, and subcutaneous injections of ether over the cardiac area were given. At 2 A.M. the skin was still cold, and showed no trace of sensibility. Five drops of nitrite of amyl were then given by inhalation, and at once the respiration began to improve. At 3 A.M. half a drop of nitrite of amyl dissolved in alcohol was injected beneath the skin, without any perceptible effect. At 5 o'clock, after six hours of artificial respiration, sensibility of the conjunctiva began to return, and the natural respiration became deeper. Gradually the skin grew warmer, and consciousness returned. In a few days the patient was well, complaining only of pain in the epigastrium, and of some pimples under the tongue. The urine contained neither albumen nor sugar. The absence of vomiting was notable; it was doubtless due to the local anæsthesia of the stomach and œsophagus. When the general anæsthesia was most profound the pupils were contracted; they dilated when the respiration had almost ceased. They contracted again on the application of the battery. Dr. Oliver was led to give nitrite of amyl by observing the general capillary spasm of the skin.—*The Practitioner*, January, 1883.

THE CHEMISTRY OF ACUTE YELLOW ATROPHY OF THE LIVER.—In a case of this disease Salkowski estimated the quantity of peptone and hemi-albumose in the liver, spleen, and kidneys. In normal conditions these substances are either absent altogether or only present in traces in the organs named. In this case the amount of peptone and hemi-albumose in the liver were respectively 3.57 and 0.71 per cent.; in the spleen 3.40 and 0.95; in the kidneys 2.56 and 0.39. The great resemblance between the decomposition of albumen in the organs in this disease and digestion with trypsin led him to search for tryptic ferment in the liver. By extracting with glycerine, however, he got no definite result; the glycerine extract dissolving fibrine but only after several hours and incompletely. In regard to the hemi-albumose, he found that Kühne was right in his statement that this body is insoluble in water. His own previous statement that it is soluble in water he now finds to be due to a slight error; the specimen he used having contained a small quantity of acetic acid.—*The Practitioner*, January, 1883.

DEATHS OF ENGLISH PHYSICIANS.—The past year brought death to the doors of no fewer than twenty-two prominent English medical men, and all were far advanced in age, the ages varying from seventy-eight to ninety-two.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, February 17, 1883.

THE ANATOMY OF THE SCROFULOUS.

Not long ago we gave a brief account of the anatomical anomalies found by Beneke in the scrofulous. These were, speaking generally, a disproportionately small size of the viscera, the lungs being excepted.

A contribution to the same subject has recently been made by Dr. H. F. Formad, and is published in the *Philadelphia Medical Times*. Dr. Formad makes no reference to Beneke's laborious researches, and is apparently not aware of them. His own views, however, are the result of much experimental investigation, and have a special interest, since they are quite opposed to any infection theory of tuberculosis.

Scrofulous persons, he states, have an anatomical characteristic, lymph-spaces which are abnormally narrow, or partially obliterated by cellular elements. This characteristic is found also in certain animals which are known to be scrofulous, such as the rabbit and guinea-pig. An examination of the connective tissue from similar regions in the cat, which is non-scrofulous, and the rabbit, will show a noticeable difference in the appearance of the lymph-spaces and the amount of cellular infiltration. Scrofulous animals have proportionately, also, larger blood-making glands and more red bone-marrow. Non-scrofulous animals can be made scrofulous by impoverished diet and confinement. The same can be done with individuals who are naturally not scrofulous.

The evidence brought forward by Dr. Formad to prove a coincident change in the blood-glands and lymph-spaces appears to us to be insufficient. The views propounded regarding the blood-making glands in scrofulous human beings are, we believe, contradicted by Beneke.

The scrofulous individual is not necessarily tuberculous, nor is it his certain fate to become so. There is needed for this an inflammation. In normally constituted connective tissue, the lymph-spaces are large enough to carry off inflammatory products, or if this does not happen, there is tissue destruction and suppuration. In the scrofulous, however, these alternatives are not presented—the lymph-spaces are blocked up, there is lymphoid infiltration, caseation, and tubercular tissue formation. Scrofulous beings can have no other than a tuberculous inflammation, although that may remain local and harmless. *Per contra*, inflammation (tuberculous) is the only means by which the scrofulous (or non-scrofulous) can get tuberculosis. "Without inflammation, no

tuberculosis," is Dr. Formad's dictum, in which we may perhaps detect something of the bias toward inflammation as a pathogenetic factor which that investigator has previously shown.

It is admitted that non-scrofulous persons or animals do sometimes become tubercular, even with normal connective tissue. In these cases, it is contended that the injuries or inoculations must be made, and so far have been found to be, in the serous membranes. In these membranes there is easily produced a blocking up of the lymph-spaces, so that the anatomical characteristics of scrofulous tissue are artificially obtained. The sequence of tuberculosis after croupous pneumonia is explained on the ground that the lining epithelium of the lungs resembles very closely a serous membrane. The reasoning here, however, is weak, and we cannot concede that the clinical phenomena of the etiology of tuberculosis are satisfactorily explained. Yet the statement that tuberculosis can only be *inoculated* artificially by bringing the virus into contact with serous membranes is important. We are informed that Koch, in inoculating his bacilli into scrofulous animals, injected it into any part of the body with successful results. But when inoculating non-scrofulous animals, he always deposited the parasites in the anterior chamber of the eye or in the peritoneum.

Dr. Formad's conclusion is that there is no specific virus of tuberculosis, but that there is a specific constitution. Inflammatory processes in the latter, however produced, lead to tuberculosis.

MEDICAL INSTRUCTION IN EUROPE.

THE *Allgemeine Medicinische Central-Zeitung*, No. 76, 1882, gives some statistics concerning the medical schools in the different countries of Europe, from which the following account is taken: In Holland there are four universities with medical schools attached. The course of study is for six years, with an examination before a royal commission at the end of the fourth and sixth years. Spain has eight universities which grant a license to practise, though the University of Madrid alone has the privilege of conferring the degree of Doctor. Only doctors are allowed to teach medicine, and any one who desires to give medical instruction must first pass a year in study at Madrid. Portugal has one university and two medical schools. The course of study is for five years, with an examination at the end of each year. All examinations are conducted by the faculty of the university. In Italy there are nine universities, with a six-years' course of study. Attendance at the lectures is for the most part obligatory. Switzerland has four universities which confer the degree of Doctor. This, however, is not a license to practise, for which a further examination on natural philosophy and the medical branches is required. The course of study is six years, and two examinations must be passed. Austro-Hungary possesses eight universities of equal rank in the conferring of degrees. Three examinations occur in the course of five years' studies. In Russia six of the eight universities possess medical faculties. At St. Petersburg there is, besides, a medico-chirurgical academy for the education of military surgeons. At the end of a five-years' course of well-arranged and obligatory studies the

candidate may pass to a degree of physician or doctor. The former grants a license to practise only, the latter authorizes the holder to teach medicine. For army and navy surgeons a further examination is necessary. Sweden has three medical schools, which grant a license to practise *only after ten years' study* and three examinations. Norway possesses but one medical school for theoretical instruction. Clinical experience is gained in the hospital in Christiania. The candidate for a medical degree is required to pass four examinations. In Denmark from six to seven years must be passed in study in the University of Copenhagen. Instruction itself is free, but an examination fee is required. The license to practise medicine is given to natives of Denmark only. In France there are three "medical faculties" besides two "écoles de plein exercice" and fifteen "écoles préparatoires." The degree of "docteur en médecine," which permits the holder to practise anywhere in the country, is granted only by the three faculties. Graduates of the other schools are called "officiers de santé" and may practise only in the department in which they have studied. Doctors who aspire to professorships must present themselves, after a further study of three years, to one of the medical faculties for examination. They then receive the title of "professeur agrégé," which corresponds to the privatdocent of the German universities.

SOME RECENT RESEARCHES ON THE PHYSIOLOGY AND PATHOLOGY OF THE STOMACH.

IN order to decide at what precise time an excess of free hydrochloric acid appears in the stomach, Dr. Edinger has recently undertaken a large series of observations. He experimented upon his own person and that of many others. It appears from his investigations (which are recorded in the *Deutsches Archiv. für Klinische Medizin*, vol. xxix.) that from three to four hours after a meal is the usual time for an excess of acid to be present in the gastric juice. Vomited matter from a typhoid fever patient was examined, and found to contain a large amount of free acid, and that, too, at a time when the fever was at its highest. This observation affords contradictory evidence of statements made by others, who assert that in febrile conditions an appreciable diminution of gastric hydrochloric acid is an invariable occurrence.

Edinger has also studied amyloid degeneration in connection with the stomach. He found that the vessels of the gastric walls were commonly implicated in the process of degeneration, but in addition the muscular coat was also frequently involved, and in not a few instances the connective-tissue structures of the stomach, and its glandular elements likewise participated in the amyloid change.

The author holds that an amyloid stomach easily becomes a dilated one; for in this change, provided the gastric muscle suffers, mechanical distention is not opposed by healthy contraction on the part of the walls of the stomach.

When ulceration supervenes in amyloid stomachs, it is the otherwise healthy portions that are primarily attacked, the amyloid matter seemingly resisting the destructive tendencies of the gastric juice. There is also noticed in

amyloid stomachs a want of free hydrochloric acid at the proper time, showing that the gastric function is materially impaired by this degenerative process. Frerichs was the first to point out a vital sign that should arouse the suspicion of amyloid infiltration of the stomach, in cases where other organs are known to be affected in a similar manner. This symptom is the loss of appetite, with occasional vomiting, while the tongue shows no coating. But Edinger very justly contends that these symptoms are quite vague and unreliable, for they may occur in a variety of other disorders. On the contrary, he has found that patients with amyloid stomachs have a natural appetite. He says, however, that the absence of epigastric pain, vomiting with a healthy-looking tongue, associated with amyloid changes in other organs, may justify a positive diagnosis.

One practical point may evidently be learned from these interesting observations. If muriatic acid is to be prescribed, with a view to aid digestion, the best time to give it would be some hours after eating, and not, as is often done, immediately after a meal.

DEATH IN NEW YORK CITY.

IT is sometimes charged, that the physician can extract morsels of comfort in contemplating the unusual prevalence of disease. If so, a study of New York City's vital statistics for 1882 will have much attraction for him.

There died in this city last year 37,951 persons, which is at the rate of 29. + per thousand. This is, we believe, a higher ratio than exists in any other Northern or Western city. The death-rate, as shown in the accompanying table, was very large at the beginning of the year. It slowly fell, reaching almost its lowest point in June.

1882.	Deaths.	Births.	Stillbirths.
January	3,498	2,278	200
February	3,298	2,092	218
March	3,481	2,506	199
April	3,395	2,042	221
May	3,353	2,150	240
June	2,871	2,065	200
July	4,482	2,060	208
August	3,329	2,469	213
September	2,579	2,365	226
October	2,588	2,471	230
November	2,461	2,292	245
December	2,522	2,531	246
Total	37,857	27,321	2,646

It then suddenly rose, and in July there were 4,482 deaths, making the enormous ratio of 41 + per thousand inhabitants. This wave of mortality gradually sank, and during November reached its lowest point, when only 2,461 deaths occurred. For the whole year the deaths have been 673 less than they were last year, despite increased population. This decrease has been almost entirely in zymotic diseases. The number of deaths from these diseases in 1881 was 13,493, against 12,522 during the year just past. As the accompanying tables show, there was a decrease in all the contagious diseases during 1882 except measles.

CASES OF CONTAGIOUS DISEASE.

Year.	Typhus fever.	Typh'd fever.	Scarlet fever.	Measles.	Diphtheria.	Small-pox.
1880 ..	2	508	3,048	3,891	3,307	67
1881 ..	568	965	7,338	3,116	5,272	1,342
1882 ..	207	684	6,594	4,733	3,842	708

DEATHS FROM CONTAGIOUS DISEASES.

DISEASES.	1882.	1881.	1880.
Small-pox	269	451	31
Measles	912	429	479
Scarlet fever	2,070	1,964	618
Diphtheria	1,521	2,249	1,390
Croup	730	1,038	910
Whooping-cough	655	286	277
Erysipelas	151	192	171
Typhus fever	66	160	3
Typhoid fever	363	446	241
Malarial fever	533	605	470
Yellow fever			1

Twenty-five persons died from accidental poisoning ; and the special records concerning these are instructive : One died from rat-poison, one from soothing-syrup, one from acetic acid, four from opium, seven from lead poisoning, two from laudanum, one from chlorate of potash, two from iodine, one from carbolic acid, one from whiskey, one from bromide of potassium, one from morphine, one from hydrate of chloral, and one from arsenic.

The whole number of suicides recorded was 199, against 166 in 1881, and 152 in 1880. Of these, 165 were men, and 34 were women ; 71 were Germans, 50 Americans, and 20 Irish.

PHYSICIANS AND THE CRIME OF SUICIDE.

In a paper recently read before the New York Medico-Legal Society, by its President, Mr. Clark Bell, some of the facts regarding suicide were summarized, and the question of its criminality discussed. The works of Forbes Winslow, Morrelli, and O'Dea have furnished to the public a great mass of statistics regarding suicide. These have shown that suicide is an integral part of human society, and is governed by certain laws, which are quite beyond the immediate reach of individual volition. They show, for example, that suicides are most numerous between the ages of twenty-five and fifty-five ; that they increase proportionately until extreme old age ; that men commit suicide oftener than women, in the proportion of two or three to one ; that men kill themselves later in life than women ; that sorrow, reverses of fortune, physical suffering, domestic trouble, hindered passion, and insanity are the more prominent causes ; that suicide and insanity are both increasing, but with no definite ratio between them ; that the diffusion of education increases suicide ; that the number of suicides varies greatly with the race, from seven per million in Portugal, twenty-six in Italy, forty in the United States, sixty-eight in England, one hundred and ten in France, one hundred and twenty-three in Prussia, to two hundred and eighty-eight in Denmark ; that the proportion in the United States is largest in California and Nevada ; and finally, that in the civilized world suicide is steadily increasing.

The question of what shall be done is partly a legal, partly a moral and medical one. The advisability of enacting laws which will make suicide a crime is discussed by Mr. Bell, who is somewhat inclined to favor such a measure. To oppose successfully this increasing practice of suicide, however, something much more powerful than legal measures will be required. And the more one studies social problems, the greater appear the duties and functions of the physician toward them. Healthy minds in healthy bodies are very nearly safe from suicide. The securing for his young patients a well-balanced and vigorous constitution is the work which the physician has to do in helping to relieve civilization of the vice of self-destruction.

CHARCOAL-FUMES AND COAL-GAS.

It is universally conceded that the growing complexities of modern civilization are correspondingly fraught with danger to life and health. The increasing number of deaths from the effects of various noxious gases furnish but a single, though quite apt illustration of this dictum. Poisoning by charcoal-fumes or coal-gas is doubtless of daily occurrence. And medico-chemical interest in such agents is a natural consequence of accidents of this kind. Accordingly, Drs. Biefel and Poleck have reinvestigated the toxicology of the agents in question. (*Zeitschrift für Biologie*, vol. xvi., 1882.) In charcoal-fumes they found carbonic oxide and carbonic acid in the relative proportions of one to twenty. The former was chiefly responsible for the poisonous properties of these fumes. Their experiments were conducted by placing animals in an atmosphere gradually contaminated with the noxious charcoal-fumes. When the oxide introduced had reached 0.44 per cent., severe symptoms of poisoning arose. Death occurred when the gas had risen to 0.62 per cent.

Coal-gas behaved in a somewhat different way. It required from 1.5 to 1.94 per cent. of carbonic oxide to produce fatal effects. In coal-gas the absence of carbonic acid, formed at the expense of the oxygen, appeared to materially modify the poisonous effects of the carbonic oxide. The effects of the latter, as compared with carbonic acid, are contrasted by the authors as follows :

Carbonic acid produced varying degrees of coma. Dyspnœa resulted, which gradually passed into asphyxia. Violent tetanic convulsions or general tremors were but rarely observed. Respiration appeared to become slowly paralyzed. Post-mortem examinations revealed dark red blood, congested, œdematous, and dilated lungs, moderately hyperæmic brain, and the right side of the heart distended with dark blood.

Carbonic oxide, on the other hand, never led to coma ; but it produced muscular weakness and transitory paresis of the extremities. Dyspnœa was not observed ; but there were convulsive expiratory efforts, and general convulsions. Autopsical inspection showed hyperæmia of the brain and its coverings, together with altered red blood in the latter. No pulmonary œdema, but vesicular emphysema. The heart was filled with liquid blood. This fluid also frequently contained bubbles of air. Finally the occurrence of subcutaneous emphysema was noted.

THE POVERTY OF MEDICAL MEN.

DR. B. E. COTTING, in an address before the Massachusetts Benevolent Society (*Boston Medical and Surgical Journal*) took a somewhat gloomy view of the pecuniary status of medical men. He said that an eminent clergyman once investigated the incomes of physicians in one of the larger cities of another State, and found that, after deducting expenses necessary to the practice of the profession, they did not annually receive, on an average, more than workmen in the same city.

He related the following anecdote:

"Rouse up," said the members of the family to one of the first physicians of France, then on his couch, sinking under most painful and wasting malignant disease—"rouse up—a patient is waiting. Go earn a few francs—there is not any bread in the house!"

We might instance the case of a distinguished surgeon of this city, widely known and justly celebrated for his skill. He died a year ago after twenty years of practice and now subscriptions for his widow are being made.

This is an extreme case, it is true, but helps to explain why even the best qualified medical men cannot always succeed. There is not only a plentiful supply of first-class practitioners in all our large cities, but the profession is year by year becoming more and more crowded. Hence competition is fiercer and the chances of brilliant success are proportionately fewer.

THE BACILLUS OF WHOOPING-COUGH.

AN interesting paper, pertaining to the pathology of whooping-cough, was lately read before the Medical Society of London, by Mr. Dolan, F.R.S., in which views were advocated which were put forth by Poulet, in 1867; by Letzerich, in 1873; and still later by Tschamer. Mr. Dolan has repeated the experiments of these former investigators, and with successful results.

Poulet, in 1867, found certain bacteria of a peculiar kind in the sputa of patients affected with pertussis; Letzerich commenced a series of investigations a few years later. The latter found constantly present in the sputum of pertussoid patients a bacterium belonging to the genus *Ustiligo*, Tul.; with this micrococcus he inoculated the tracheal mucous membrane of tracheotomized rabbits and noted the results. He invariably produced a spasmodic catarrhal affection resembling whooping-cough, and he observed that the bacteria do not penetrate the epithelium, but live on the surface of the mucous membrane, to the detriment of the latter.

Tschamer, of Gratz, working in the same department of micro-pathology, has lately found, in the expectoration of pertussis, a microphyte, which he identifies with a black mould which develops on orange-peel. This he thinks that he has proved by different cultures. Satisfied of the identity, he took some of the black powder which constitutes the mould of orange-peel and experimented with it on himself, inhaling the powder as deeply as he could. At first no effect was observed, but after eight days he began to have convulsive fits of coughing, and expectorated the fungus in abundance.

He explains the phenomena of whooping-cough in this way. After an incubation of seven days, these microphytes determine an irritation of the bronchi which

induces catarrh and spasmodic cough; then, as the irritation increases, the expectoration becomes more abundant and eliminates the fungoid organisms.

Dolan, in repeated experiments, found that by inoculating rabbits with the sputa of whooping-cough patients, he not only induced a catarrhal spasmodic affection, but the death of the animal generally ensued. Inoculation with the blood of such patients was without effect. This certainly seems to confirm the conclusions of Letzerich, that the *materies morbi*—be it a bacillus, or be it what it may—lives on the surface of the epithelium, and does not get into the blood.

Dolan does not claim to have arrived at certain knowledge respecting the special bacteroid for which causes pertussis.

The theory, then, is a simple one, that whooping-cough, like other contagious diseases, is the product of germs, which, given off in the breath of pertussoid patients, are inhaled by persons of proper susceptibility, and set up irritation of the respiratory epithelium; the result is the vascular and nervous disturbances, and other phenomena which characterize whooping-cough. The severe constitutional disturbance which sometimes attends the disease is a secondary effect.

Mr. Dolan suggests nothing new with regard to the treatment of this affection (which must be largely directed to the palliation of symptoms); but adds that if the dependence of pertussis upon a specific virus, be the true explanation of its pathogeny, the lines on which its rational treatment and prophylaxis are to be pursued become clearer and more hopeful.

SANITARY PROTECTIVE ASSOCIATIONS.

SANITARY Protective Associations seem to be the rage in Great Britain. A third has recently been founded in Liverpool, called "The Northern Sanitary Association," of which the Earl of Derby is president. This would indicate that the London and the Edinburgh associations, which have been in existence for some time already, are in a flourishing condition. The services of these associations are most valuable to vendors, purchasers, and intending tenants of house property, since they provide good practical advice on sanitary matters at a moderate cost. They advise, inspect, and superintend, but do not undertake the execution of work, thereby avoiding interference with builders and contractors. Associations of this kind would find a very wide field in the United States, and we hope that some will be in running order before the summer exodus to the seaside and the country takes place.

THE PRACTICE OF MEDICINE IN NEBRASKA.

THE law regulating the practice of medicine in the State of Nebraska is, as might have been expected under the circumstances, reported to be virtually a failure, so far, at least, as affording protection to the people from the impositions of quacks. There is no provision for any tribunal by which may be determined the genuineness of a diploma, or license. It is, therefore, wisely recommended to establish a State Board of Health, with authority to refuse its certificate to any person not properly

qualified to practise medicine, and also to order before them for examination any one practising medicine, be he a graduate or not.

The total number of graduates of all schools practising in the State is 567, practising under the ten years provision of the law, 206; "first course students," 38; of less than ten years' practice, and in open violation of the law, 27; number practising that are not registered, 40; number of fraudulent diplomas detected, 87.

News of the Week.

AN ASYLUM SUPERINTENDENT SUES FOR DAMAGES.—Dr. Wylie, of the Dixmont Insane Asylum, has begun a libel suit against the Erie (Penn.) *Herald* for \$40,000 damages for publishing an interview charging cruelty and injustice to the inmates of the institution.

FEES OF THE HEALTH OFFICER OF THE PORT OF NEW YORK.—The following resolution has been introduced into the New York Assembly:

Resolved (if the Senate concur), That the Congress of the United States be and is hereby requested to establish by law such just and uniform quarantine fees for the port of New York, and for all ports of entry in the United States, as a conference of the representatives of the State Boards of Health of the maritime States may recommend, or as Congress in its wisdom may direct after full knowledge of the irregular quarantine fees now imposed by law, the object of this resolution being to establish economical and efficient commercial and health service in the principal quarantine ports of the country.

WHOLESALE BODY SNATCHING.—It is stated that one hundred and fifty bodies have been stolen from graveyards in the vicinity of Montreal during this winter, one-half of which were sent to medical schools in the United States.

A LADY DOCTOR FOR THE LONDON POST OFFICE.—Mr. Fawcett is said to intend appointing a lady doctor for the lady employees in the London Post Office. The *Lancet* is stirred up to protest against such action.

DR. ANDREW CLARK has recently been elected President of the London Clinical Society. Dr. Clark is the medical attendant of Mr. Gladstone, and *Punch* publishes his caricature with the following lines:

"There was a sharp doctor, and what do you think?
His simple prescription was 'Wittles and Drink.'
Wittles and Drink—most important is diet—
And mind, Grand Old Man, you must keep yourself quiet."

MIXING ITS ANATOMY.—Our esteemed contemporary, the *British Medical Journal*, has been advertising a work entitled "Diseases of the Prostate in Both Sexes," by David Jones, M.D.

SYPHILIS SPREAD BY A MIDWIFE.—Much excitement was caused recently in Sheffield, England, by the trial of a midwife on the ground that she had communicated syphilis to about thirty married women, and to two infants, while in the discharge of her professional duties.

A NEW ITALIAN JOURNAL especially devoted to children's diseases, and called *Archivio di Patologia Infantile*, has just been started by Prof. Luigi Somma, of Na-

ples. It is to be published bi-monthly, and includes on its editorial staff as many as twenty-five professors and practitioners.

THE LANCET AND NEW YORK PHYSICIANS.—The three leading articles in a recent issue of *The Lancet*, were contributed by New York physicians.

MEDICAL RELIEF IN PARIS.—The Municipal Council of Paris recently voted the sum of \$600,000, of which \$400,000 is to be spent in the improvement of existing hospitals, while \$200,000 will be devoted to erecting new establishments for the relief of the city's sick poor.

THE BROOKLYN HOSPITAL SATURDAY AND SUNDAY COLLECTION for 1882-83 amounted to \$3,925.37, to be divided among seven hospitals. This was the first year, and is an excellent beginning.

FACTS FROM THE CENSUS.—A few copies of the advance sheets of the "Compendium of the Tenth Census" have been distributed. Some of the facts therein contained we publish here prior to a more extended consideration of the complete volume.

The defective classes, which include the insane, idiotic, blind and deaf-mutes, numbered in 1870, 98,484; in 1880 the number was 251,698. The increase of population was only thirty per cent., that of the defective classes apparently one hundred and fifty-five per cent. The ratio of this class to the whole population was in 1880 as 5,018 to each million. This startling increase, however, is only apparent, as it is admitted that previous census reports were very inaccurate.

The total number of the insane is given as 91,997, of whom only forty-four per cent. were in hospitals. These are nearly the same estimates as those made by Dr. Dana in a paper read before the National Association for the Prevention of Insanity, a year ago. Among 76,895 idiots, three per cent. were in training schools for the feeble-minded; of 48,928 blind persons, less than four and one-half per cent. were in schools and industrial homes for the blind; and of 33,878 mutes, nearly sixteen per cent. were in schools established for them.

It appears from the report that insanity in the United States attacks women more frequently than it does men, but men on the other hand are more liable to be idiotic, blind, or deaf. The negro population is much more liable to idiocy than insanity. Both the negro and the foreign population are singularly more liable to blindness than to deafness. The tendency of the foreign population to insanity is especially worthy of attention. "It is startling to know," says Mr. Wines, "that of 50,000,000 of inhabitants over 400,000 are either insane, idiots, deaf-mutes, or blind, or are inmates of prisons, reformatories, or poor-houses. If to these we add the out-door poor and the inmates of private charitable institutions, the number will swell to nearly or quite 500,000, or one per cent. of the total population."

The death-rate of the United States, as established by the number of deaths recorded, was 15.1 to the thousand, a rate decidedly higher than those given in the censuses of 1860 and 1870. This does not indicate, however, any actual increase in the rate, but shows that the returns in 1880 were more complete. Adding estimates of deficiencies, the agent in charge estimates the actual death-rate at somewhere between seventeen and nine-

teen per thousand. The rate in England in the same year was twenty and one-half. Of the total number of deaths reported, which was 756,893, the cause in 91,551 cases was consumption; diphtheria caused 38,398 deaths; enteric fever, 22,905; malarial fever, 20,261; and accidents or injuries, 35,932. The death-rate of the colored race is much greater than that of the white.

FINAL REPORT UPON THE HOSPITAL COLLECTIONS.—The detailed report regarding the hospital Saturday and Sunday collections has been published, and is as follows:

Episcopal churches	\$11,898 55
Presbyterian churches	3,329 19
Baptist churches	392 69
Reformed (Dutch) churches ..	394 69
Lutheran churches	241 40
Methodist churches	203 46
Unitarian churches	221 68
Swedenborgian churches	147 00
Reformed Episcopal churches ..	50 00
Congregational churches	25 00
Synagogues	1,556 17
Total for churches	\$18,459 78
Trade collections	8,635 40
Hebrew lodges	235 00
Box collections	857 71
Individual donations	2,141 97
Balance from last collection ...	237 16
Total	\$30,567 02

In addition to this are sums from other sources, making the total amount \$33,862.72, against \$42,535.45 in 1881, \$44,371.97 in 1880, and \$26,455.07 in 1879.

The falling off in receipts is thought to be due to exceptional causes which will not be present next year. It appears that while there was a very liberal advertisement and a great display of yellow boxes, there were few successful attempts to secure the co-operation of any but Episcopal churches. The collection was essentially an Episcopal one, so far as the churches are concerned. It will probably remain so until a thoroughly representative Board of Managers takes the matter in charge. A promising feature in the present year's statistics is the increase of the trade collections.

INVESTIGATING A HOSPITAL.—The Marine Hospital at Cleveland is being investigated by Dr. Geo. Parviance, one of the surgeons of the service. The charge is that a contractor who had the lease of the hospital from the Government and formed a Hospital Association to manage the institution, ostensibly for charity, used it to make money by neglecting the patients, failing to give them proper medical treatment, and depriving them of nourishing or wholesome food.

NEW YORK CITY VITAL STATISTICS.—There were 2,818 deaths reported during the month of January. The deaths from contagious diseases were as follows: measles, 64; scarlet fever, 75; diphtheria, 108; croup, 73; whooping-cough, 27; typhoid fever, 17; cerebro-spinal meningitis, 23; and malarial fevers, 23.

PASTEUR AND KOCH.—Dr. Koch has published his reply to Pasteur, as he announced that he would do at the session of the Geneva Congress. Koch takes the ground

that "it is not yet proved that all infectious diseases are parasitic in character, but that the parasitic character must be proved in each case separately." As a model of how such proving should be done, he modestly cites his own experiments with the tubercle bacillus. He criticises the methods adopted by Pasteur in studying rabies and glanders, and denies that that experimenter's conclusions regarding them have been established. Koch also claims priority in regard to the discovery of the cause of anthrax and denies Pasteur's statements regarding the mode of propagation of that disease (*i.e.*, by the agency of earth-worms). Regarding preventive inoculations, Koch states that while some bacterial diseases may be so prevented, there are others, like gonorrhœa and erysipelas (?), against which one cannot be protected. Koch considers that Pasteur's claims for the value of preventive inoculations are exaggerated, and that his methods are cumbersome and defective. It remains now for Pasteur to say a word.

A CONSCIENTIOUS DRUGGIST.—Some weeks ago a druggist in Burslem, England, had carelessly served a customer with poison instead of magnesia. He summoned the bellman as soon as the mistake was discovered and sent him about the streets warning the unknown purchaser not to use the deadly drug. This is a rather novel way of neutralizing personal error, as it may be called, but it was successful.

A CINCINNATI PHYSICIAN has been sent to the Work-house for thirty days for cruelty to his family.

FIVE STUDENTS of the College of Physicians and Surgeons, and two of the University of Maryland, have been attacked by small-pox during the present winter. Two of the former have died of the disease. The others are progressing well toward recovery.

GRANT ON HOMŒOPATHY.—U. S. Grant, when asked to sign the petition in favor of making all physicians equal before the law in the Government service, said he would "give homœopaths no encouragement directly or indirectly!"

THE CARTWRIGHT LECTURES OF THE ALUMNI ASSOCIATION OF THE COLLEGE OF PHYSICIANS AND SURGEONS for the present year will be delivered at the Hall of the Young Men's Christian Association, corner of Fourth Avenue and Twenty-third Street, by Dr. W. T. Belfield, of Chicago, on the evenings of February 19th, 21st, 24th, and 27th, at eight o'clock. Subject: "The Relations of Micro-organisms to Disease."

CIGAR-MAKING IN TENEMENT HOUSES.—At the meeting of the Board of Health last week, the Commissioners condemned Assembly bill No. 173, to prevent cigar-making in tenements, which bill was reported to have their support. They declared that such work was not detrimental to the health of the tenement house population, and directed that resolutions to this effect be sent to the Governor, the President of the State Senate, and the Speaker of the Assembly.

THE DANGER OF ADMINISTERING ETHER IN DISEASES OF THE KIDNEY.—Mr. Lawson Tait's observations regarding this point, mentioned in a previous number of THE RECORD, merely corroborate those originally made by our distinguished townsman, Dr. Thomas Addis Emmet, as long ago as 1872.

Reports of Societies.

MATERIA MEDICA SOCIETY.

F. P. FOSTER, M.D., PRESIDENT, IN THE CHAIR.

VIBURNUM OPULUS IN DYSMENORRHOEA.

THE paper of the evening, on "Viburnum Opulus," was read by its author, DR. A. E. M. PURDY. The genus viburnum of the natural order caprifoliaceæ furnishes two plants used in medicine, viz., viburnum prunifolium and viburnum opulus. The first has been quite extensively used, is described by numerous observers, and has obtained a place in the forthcoming revision of the United States Pharmacopœia. The second, however, has received but little professional notice, and its literature is meagre and unsatisfactory. Believing the viburnum opulus to be more certain in its action than its companion of the same group, the author proposed to present some points in its history and some of the clinical results of its use in dysmenorrhœa. After speaking of its botany and history, he took up its pharmacy and chemistry. For medicinal purposes is employed the bark of the root, shrub, and its limbs (fresh bark being preferable). From this a tincture is made with alcohol of 75 or 80 per cent. (Hale). The tincture should have a dark red color and a peculiar acid odor not unlike that of valerian. Referring to its therapeutic properties and uses, the author quoted Hale, who recommends high cranberry as a powerful anti-spasmodic. In virtue of this property, says this writer, it is known among American practitioners as cramp-bark. It is very effective in relaxing cramps and spasms of all kinds, as asthma, hysteria, cramps of the limbs and other parts in females, especially during pregnancy. It is said to be highly beneficial to those who are subject to convulsions during pregnancy or at the time of parturition, preventing the attacks entirely if used daily for the last months of gestation. In the treatment of spasmodic dysmenorrhœa, for which variety this remedy is especially indicated, Hale prescribes of the tincture, a few drops a day for a week previous to the expected period. When the pains begin, he gives it every half hour, or every quarter if they be severe. He has found it equally useful for the severe false pains preceding normal labor and often rendering the woman's life a torture for weeks. In after-pains it is of great value, and should be given after each pain. Cramps in the abdomen and legs of pregnant women he was able to quickly control by its use. He claims that it will prevent miscarriage if given before the membranes are injured and when the pains are spasmodic and threatening. The use of the viburnum opulus for the relief of dysmenorrhœa, said Dr. Purdy, does not seem to have originated from professional sources. It has been in domestic use for a very long period as a remedy in the painful affections of women. Hale first gained his knowledge of the plant from its domestic employment. In neuralgic and spasmodic dysmenorrhœa he has yet to meet with a single case in which it has failed to cure, and states: "So confident have I been of its almost marvellous powers, that I have taken pains to look up some old cases that I had dismissed years ago as incurable, in order to test the remedy on them. In every instance so far it has cured these obstinate cases. Its sphere of action seems to cover about the same grounds as galvanism." In spasmodic affections of other organs, the same writer predicts its usefulness. The question is whether it acts through the motor nerves or directly upon the muscular tissues. It may prove to be a spinal remedy. Dr. Meyer, of Wilkesbarre, Pa., in his pamphlet on "Specific Medication," states that viburnum opulus, or high cranberry, and viburnum prunifolium or black haw, seems to be anti-spasmodic, and to have a specific action upon the uterus. He has only used the first named. Its employment has convinced him that it is a uterine sedative, and often a

remedy for neuralgic dysmenorrhœa and for the commonly associated spinal irritation. He gave it in doses of five to ten minims of the concentrated tincture for these conditions, and also as a preventive of threatening abortion. He believes that in the majority of cases it has accomplished the object for which it was given. Dr. Charles E. Hall (*Philadelphia Medical and Surgical Reporter* for June 22, 1878), a number of whose cases the author abstracted, states in conclusion that many more instances could be given to show the positive effects of the drug, and predicts a cure when the pain is spasmodic and neuralgic, palliation when it is congestive or pseudo-membranous. He also used it in menorrhagia with intense crampy pain, and obtained speedy relief in cases of uterine colic. The only other allusion in literature the author could find was a brief statement on page 13 of "Piffard's Materia Medica and Therapeutics of the Skin." Here it is stated that dysmenorrhœa is sometimes promptly relieved by pulsatilla and viburnum opulus.

Dr. Purdy then narrated a number of cases of his own, which led him to conclude that viburnum opulus is a powerful uterine sedative. He is satisfied that, if preparations of the fresh drug be used, many cases beyond the reach of any therapeutic aid, except opium, might be relieved, and more positive results obtained from its use than from the employment of viburnum prunifolium. He had been using a preparation similar to the abstract of the new Pharmacopœia. One grain equals in strength two minims of the tincture. The latter is made from one part of the fresh drug to two parts of alcohol.

DR. FARNHAM had had no experience in the use of this species of viburnum, but had obtained good results from the viburnum prunifolium. He had employed it in doses of a fluidrachm of the extract three times a day.

DR. PURDY stated that he had used the viburnum opulus abstract in five-grain doses.

DR. FARNHAM related the case of a lady who had aborted six times, and had been subjected to a variety of treatment. The accident always occurred before the third month. Being put upon viburnum prunifolium, she went on until the sixth month. Then, at a time corresponding to a menstrual epoch, death in her family caused her to be hurried out one stormy night and taken quite a distance in a carriage. Premature delivery took place, the child being born alive and living twelve hours. In the next pregnancy no other remedy was used, and no local treatment employed. She was told to rest four days every month at the periods corresponding to menstrual epochs, and to attend to ordinary hygiene. She went on to full term, and gave birth to a child weighing twelve pounds. Having had excellent results with viburnum prunifolium, he had used that to the exclusion of the viburnum opulus.

DR. CASTLE had used viburnum prunifolium, and had found considerable difference in the activity of the fluid extracts generally used. A good fluid extract gave pretty good results in doses of half a drachm repeated at intervals of three hours for dysmenorrhœa. He had only used it twice for the purpose of arresting threatened miscarriage. In one case it seemed to have secured a good result; in the other, small doses of ergot were also employed, so that no definite conclusions as to its efficacy were possible. While speaking of dysmenorrhœa, an observation had occurred to him bearing upon the medical treatment of many cases of this affection. He had seen what might account for the reputed efficacy of any drug tried for a limited period. In many cases he had noticed that women would suffer much from dysmenorrhœa one month, while the next they would be free from pain. On the following period they would again be much distressed, to be again comfortable on the subsequent epoch, and so on. After one attack of dysmenorrhœa they would take medicine, and the next period would be painless, the relief afforded being attributed to the remedy. It would then be abandoned, directions of the physician would not be followed out, and the follow-

ing month the old difficulty would arise. Then their experience would lead them to again resort to the remedy, with the result apparently of once more procuring a quiet time.

DR. PURDY stated that he administered as much of the abstract to a dose as could be put on a five-cent piece (*i.e.*, about five grains).

DR. CASTLE remarked that each grain of the abstract represented two minims of a fluid extract, each minim of which corresponded to one grain of the crude drug; the abstract was accordingly twice the strength of the crude drug.

DR. JOHNSON had not had much experience with *viburnum opulus*, but had used the *viburnum prunifolium* to some extent. In dysmenorrhœa, however, although cases showed a decided effect from the drug, his experience with this trouble had been of such a nature as to render him rather suspicious in regard to the virtues of the remedy. There seemed to be cases of dysmenorrhœa in which the pain appeared to be diminished on the production of a strong impression upon the mind of the sufferer. He had given minute doses of *pulsatilla* in a case where he could not make himself believe that this drug had really exhibited any of its therapeutical action, yet the woman had painless periods. One young lady, hysterical and broken down, suffering from pain so severely every month that she was prostrated, was ordered to take small doses of *pulsatilla*, being assured at the same time that this would relieve her. It did, and relief was complete. In those cases in which *viburnum* had been given for months with gradual diminution of pain, the remedy certainly did seem to possess therapeutical value.

DR. PURDY again drew attention to one of the cases mentioned in his paper. The patient was a seamstress who had had a hæmatocele for six or eight months. Pain, aggravated at the menstrual periods, had been controlled by opium. *Viburnum opulus* afforded relief without opium.

DR. JOHNSON asked whether rest had been insisted upon.

DR. PURDY stated that the patient sewed and embroidered for a living, and endeavored to do nothing else during the employment of the remedy.

DR. JOHNSON inquired whether the diminution of pain might not have depended upon diminution in size of the exudation.

DR. PURDY had noticed no such diminution in a number of examinations made.

DR. JOHNSON thought that if the decrease in the amount of pain was not due to a diminution in size of the hæmatocele, it perhaps depended upon the fact that the woman had become accustomed to its presence.

DR. PURDY agreed with Dr. Johnson that such an explanation might with reason be urged. He referred to the astonishingly long list of remedies brought forward in the "National Catalogue" for the cure of dysmenorrhœa.

DR. JOHNSON did not wish to be thought a doubter, but it seemed to him that it was exceedingly difficult to prove the efficacy of any drug in dysmenorrhœa.

DR. PURDY had been using the *viburnum prunifolium*. When Dr. Piffard suggested the *viburnum opulus*, he took up the latter and employed it. He had found that it gave him better results.

DR. WEBSTER inquired for the situation of the hæmatocele.

DR. PURDY stated that it was well down in the pelvis, pressing upon the rectum—a pelvic hæmatocele.

DR. WEBSTER stated that he had no experience in the use of the drug at all, but asked whether it might be made use of in ophthalmological practice in treating spasm of the orbicularis muscle.

DR. PURDY replied that Hale spoke very enthusiastically of it in all forms of spasm.

DR. FARNHAM had found that books attributed to it a selective action on the uterus.

DR. PURDY had Hale's authority for its efficacy in

heart cramp. *Viburnum opulus* was not an unsafe medicine, it acted as a tonic, had no nauseating taste, was non-irritating, and could be conveniently given in the form of a powder. In judging of its value, one definite preparation should be used.

DR. CASTLE regretted that the abstract unfortunately was a new preparation. There were different abstracts in the market. He could not find in the literature what dose to use.

DR. JOHNSON suggested that it would be better to use a tincture of the remedy.

DR. FOSTER was very happy to have presented positive and well-arranged testimony to the value of *viburnum opulus* in dysmenorrhœa. He had not used the remedy himself, for lack of opportunity, and perhaps for the reason he was under the impression that *viburnum* was not expected to do good in dysmenorrhœa, except in that form which is accompanied by profuse menstruation. He had not had a case of that kind for the last few months. He had used *viburnum prunifolium* a good deal, and always as Dr. Castle prescribed it—in the form of a fluid extract in doses of half a drachm three times a day. Lately he had not employed it to any extent. He was pretty well convinced that it possessed some efficacy. He administered it in cases of dysmenorrhœa accompanied by excessive menstruation. Quite recently he came to the conclusion that it had no effect whatever, and as it was a very nauseous drug, he had almost concluded to discard it. In looking over his notes, however, he found one case in which it produced good results, that was all, he thought. He was, and had been for some time, thoroughly imbued with the idea, so well expressed by Dr. Johnson, that dysmenorrhœa was in very many cases relieved by mental impressions. He had seen illustrations of this over and over again. He had frequently noticed that patients would feel comfortable for one or two periods, then nothing would give relief. He had seldom observed the alternations mentioned by Dr. Castle. These had been referred to the alternating action of the ovaries, one acting one month, the other the next. If the dysmenorrhœa was ovarian in pathology, and but one organ affected, these alternations of pain and absence of suffering were to be easily explained in accordance with this doctrine. It might have been possible that he had not obtained a good sample of *viburnum*. He had never, however, designated any particular preparation in his prescriptions, and as these had been put up in various parts of the city, he ought to have procured a good specimen occasionally. His patients objected to *viburnum prunifolium* as vile to the taste, most of them refusing to take it for any length of time. As to *viburnum opulus*, he hoped it might prove to be superior to its congener. He should specially investigate it, using the abstract, which was a good preparation for those wishing to dispense the drug themselves. In the matter of the case of hæmatocele, of which Dr. Purdy spoke, he could not see how a drug which had no hypnotic or anodyne effect, should be efficacious, how a remedy that had no action upon the hæmatocele should relieve the pain caused by it.

DR. PURDY referred to a case mentioned by Hale, in which opium had been used, and then *viburnum opulus*, as a substitute. He had administered the remedy at a venture in this case.

The Society then went into executive session.

NASAL PHYSIOLOGICAL CONDITIONS.—The nasal protuberances of the citizens of St. Louis must present some striking physiological peculiarities, to judge from the following remarks of one of their local savants: "In China they always vaccinate people on the tip of the nose, and when there is danger of an epidemic the whole city gets vaccinated at once. It is said that after the things begin to 'take' it is impossible for an American traveller to realize that he is not in St. Louis."

NEW YORK ACADEMY OF MEDICINE.
SECTION IN OBSTETRICS AND DISEASES OF WOMEN.

Stated Meeting, December 28, 1882.

HENRY E. CRAMPTON, M.D., CHAIRMAN.

DR. A. S. HUNTER was elected Chairman and DR. H. GRISWOLD Secretary for the ensuing year.

DEFORMITY OF THE PELVIS—INDUCTION OF PREMATURE LABOR.

DR. GRISWOLD reported a case as follows: In the spring of 1880 he was called to assist two of his professional brethren in a case of difficult labor. The patient was an Irish woman, twenty-five years of age, muscular and well-proportioned, who had been married four years. She had a still-birth at seven months, and a second still-birth at full term. She had been in active labor three days, the membranes having ruptured early. The pains had been hard but were then very feeble. The breech presented with the back in the hollow of the sacrum. The parts were clammy, and oil or lard failed to remove the rubbing sensation as the fingers were passed into the vagina. Under chloroform the fetus was delivered. Its surface was macerated, and the epidermis peeled off under pressure of the fingers. The vagino-rectal wall was torn for three and a half inches. The parts were cleaned, placed in apposition, and silver-wire sutures were introduced. The bladder was evacuated with the catheter and frequent carbolized vaginal injections were prescribed.

On the second day following delivery the nates were found excoriated and the right labia presented a blistered appearance. On the fourth day erysipelas was ushered in with a chill. Around each suture a slough was forming and they were removed. The woman recovered in about two weeks with the loss of a portion of the vagino-rectal wall. The cause of the difficult labor was found to be in the narrowing of the diameter between the rami and an approximation of the ischial tuberosities, forming what is usually called the masculine pelvis. It is a modification of the infantile, and according to Dr. Barnes, of the Royal Maternity Hospital, England, "is accompanied by development of unusual muscularity, corresponding to the laborious employment of the individual." This delivery occurred in April. In December following she was operated upon for restoration of the integrity of the rectum. The edges of the rent all around for a full quarter of an inch were vivified, and the needles carried through so as to just avoid the edges of mucous membrane of the rectum. Incisions along the lateral walls were necessary in order to remove the tension upon the sutures, and the surfaces thus made were left to granulate. Union took place throughout, save at the superior portion of the perineal body, about an inch and a half above the anus. Here on the eighth day a fecal fistula was established. Hardened feces, making free use of the finger necessary, caused much annoyance until the expedient was tried of administering a teaspoonful of compound licorice powder in half a glass of water at bedtime, followed by an enema of flaxseed tea and sweet oil in the morning, when no further trouble was experienced. It is now his habit to use this method in all cases of operation about the perineum. The daily action of the bowels did not seem to retard the healing of the fistula, although fecal matter frequently passed into the vagina. The occasional application of nitrate of silver was all the treatment that seemed necessary to complete the union. At the end of the month the fistula had entirely closed, and the patient rapidly gained in strength and flesh. Fifteen months later she again became pregnant, and about the first of the present month we decided to induce labor at seven and a half months of pregnancy, with a view of preserving the integrity of the parts gained in the last operation and also, if possible, obtaining a living child. At the suggestion of Dr. A. S.

Hunter, three or four small sponge-tents were introduced into the os, side by side, which in six hours was dilated sufficiently to admit the smallest Barnes dilator. This was filled by a Davidson syringe and the two larger sizes soon followed. The internal os, almost its entire length, was dilated by these means to easily admit three fingers. A bag of waters presented and pains in the back commenced. Mechanical means were then discontinued, in the expectation that nature would complete the labor, but the pains gradually subsided, and in twenty-four hours all was quiet. A No. 3 Barnes dilator was then introduced into the uterus, inflated, and left overnight. Uterine contractions expelled the bag and labor ceased. A No. 9 bougie was then introduced for five inches between the membranes and the uterus. It remained overnight without producing any effect. As the os was then dilatable, and all previous efforts had failed, rupture of the membranes was practised. Twelve hours later labor came on and the pains were uniform and progressive. The nates presented. The progress was arrested by strong cicatricial bands in the regions that had been left to granulate in the operation. These bands were divided with a blunt bistoury; no hemorrhage followed, and the delivery of a dead fetus was effected twenty-four hours after labor had commenced. Its presenting parts were much excoriated by friction. The mother made a rapid recovery and suffered no inconvenience from the incisions that were made. The after-treatment consisted in a complete washing out of the uterus, after the expulsion of the placenta, with a two per cent. solution of Calvert's carbolic acid. Her diet was sustaining and lactation was restrained by the application of stramonium ointment and powdered camphor to the mammae.

It was possible that had labor been resorted to two weeks sooner a living child might have been saved. One interesting question suggested by the case was, How can labor certainly be induced? For a week beforehand she had resorted to the hot douche, and then the hot and cold alternately, with no avail. Besides, the various recognized methods already mentioned were adopted, but nothing was effected until the membranes were ruptured, and this only after twelve hours of delay.

DR. ISAAC E. TAYLOR thought the cases in which there was simply narrowing of the antero-posterior diameter of the pelvis differed from those in which the pelvis was equally or generally contracted, or, as he preferred to call it, "naturally faulty." He then referred to a case in which the antero-posterior diameter was two inches and a half, the pelvis being substantially what is known as the male pelvis. The description given by Dr. Griswold led him to the conclusion that there was narrowing of the inferior strait in the case, and that it was probably reduced to two inches and a half or three inches in diameter. He thought that these differences should be kept clearly in mind, and made distinct when considering Cæsarean section, laparo-elytotomy, craniotomy, and cephalotripsy. If the antero-posterior diameter was only an inch and three-fourths, or two inches, and the head of the child was transverse, it would probably be better to perform craniotomy and cephalotripsy rather than resort to Cæsarean section. There might, however, be exceptional cases. The reason was that as the head was transverse in the pelvis it was in a favorable position, so that after craniotomy the base of the head could be crushed with the cephalotribe. He very much questioned as to whether delivery could be completed by means of the cephalotribe unless the base of the skull was crushed several times. He doubted also whether in one out of twenty cases the base of the skull was crushed with that instrument, but he believed that the head could be easily delivered by a slight manipulation, namely, by tilting the base of the head, and in that manner the operator was able to bring it down readily. He then referred to a case in which, after craniotomy was performed, he introduced the blunt hook, tilted the head, and the labor was completed very promptly. At the next labor the same patient

preferred Cæsarean section. Porro's operation, however, was performed, and the uterus and ovaries were removed, and the patient passed on very well until the twenty-eighth day when phlegmasia dolens developed. From this she recovered, but disobeying orders, she got up, and suddenly died of cardiac thrombosis.

The generally contracted pelvis, the naturally faulty, the equally contracted pelvis, ranging from three and a half to three and three-fourths inches in diameter, required Cæsarean section when early performed; or if the labor had existed for some time, laparo-elytrotomy might be preferable to Cæsarean section. In Dr. Griswold's case, where the diameter of the inferior strait was so narrow, the child already being dead, there was no proper way by which delivery could be completed, except by breaking up the base of the skull or tilting the head.

With regard to methods of producing premature labor there were none which he had not employed. He thought sponge-tents were objectionable because of the length of time required. If the uterus could be pushed down, he would first introduce the finger, as it was the best dilator which could be used. After this a small Barnes dilator might be used, which might be succeeded by others of larger size. He was unable to recall a case in which this method had failed. As a rule, labor could be established from thirty-five to forty minutes after the first Barnes dilator was introduced.

His conclusions were, that the generally contracted, the naturally faulty pelvis demands Cæsarean section if performed early; or laparo-elytrotomy might be preferred if labor had existed for some time.

The infantile and male pelvis probably would require in some cases laparo-elytrotomy if the labor was far advanced. In the pelvis in which the antero-posterior diameter at the superior strait was two or two and a half inches, he would perform craniotomy and cephalotripsy.

METHOD OF MEASURING THE DIAMETERS OF THE PELVIS.

Dr. Taylor then spoke of the method to which he had frequently resorted for measuring the diameters of the pelvis. Introduce the hand, and for measuring the transverse diameter turn the thumb toward the right or toward the left, and then estimate the difference between the diameter of the pelvis and the width of the hand, which could be done with the thumb. To measure the antero-posterior diameter, turn the hand, the thumb toward the pubis and make the estimate in a similar manner. He believed that when the hand could be introduced, the operator could get a more correct view with regard to the antero-posterior as well as the transverse diameter than by any other method which could be employed. If after introducing the hand into the pelvis it could not be rotated freely, it was safe to assume that the pelvis was generally contracted. He believed that the so-called justo-minor pelvis, or what he denominated the naturally faulty pelvis, occurred much more frequently than had been supposed.

DR. C. JEWETT, of Brooklyn, referred to a case as follows: An Irish woman, thirty-five years of age, a primipara, had been in labor several days. The physician in charge had been in attendance from time to time, and had given ergot during the last twenty-four hours, supposing that delay was due to inertia of the uterus. When Dr. Jewett was called, he found the abdomen tympanitic and the uterus firmly investing the fetus. The occiput was presenting antero-posteriorly, and the head was arrested at the outlet of the pelvis on account of the narrowness of the inferior strait. The actual measurement of the transverse diameter at the outlet was three and one-sixteenth inches, the pubic arch measured fifty-eight degrees. These were the measurements made upon the pelvis after it had been removed, cleaned, and dried. The physician in attendance had attempted to deliver with the forceps, but had been unable to do so. Dr. Jewett subsequently, however, attempted to apply the forceps, but the space was not sufficient to admit the

instrument and permit it to be locked. He subsequently attempted to apply Dr. Lusk's cephalotribe, but failed. The woman was delivered by craniotomy and died sixteen hours afterward. In this case also the head of the child was unusually large and firm. He believed that had he seen the case before the head had engaged and become so firmly impacted, he should have performed laparo-elytrotomy.

With regard to the induction of premature labor, the method which he had usually employed was to introduce a flexible bougie into the uterus and leave it in position overnight. In the subsequent treatment he had sometimes resorted to Barnes' and sometimes to Molesworth's dilators. He had not had any difficulty in inducing labor in that manner. Manual dilatation was certainly a most excellent method, but he had quite uniformly succeeded in the manner indicated.

DR. A. S. HUNTER remarked that he had used sponge-tents for the induction of premature labor in a few instances, and had had reason to be satisfied with the results. He thought that if the os was filled completely with them the results desired could be obtained very readily, and, if there was sufficient time, he would not hesitate to resort to that method. For example, in Dr. Griswold's case, where there was nothing to indicate special haste, he advised the use of sponge-tents. In cases in which results must be obtained more speedily it might be necessary to resort to other measures.

He certainly would perform laparo-elytrotomy rather than craniotomy and cephalotripsy if the child was living and if the life of the child would necessarily be sacrificed by attempting to deliver it through the pelvic canal.

DR. WARNER, of Boston, remarked with regard to the induction of premature labor, that he had never resorted to any means except manual dilatation, and had always succeeded. He thought that method was much the safest, and in his experience it had always acted promptly. After introducing one finger another might be made to follow, never changing position until he had taken hold of the child's feet and completed the labor. The advantage of manual dilatation was that the operator could know exactly what he was doing, could feel just how much force he was using, could determine how much the womb was yielding, and could estimate very precisely the amount of pressure which was being made.

DR. GRISWOLD remarked that the objection which he had to introducing the hand in his case was the condition of the tissues in the vagina. Moreover, the uterus was so high up that it was only with a great deal of pressure that he was able to reach the os. Under the circumstances where almost all the perineum was composed of cicatricial tissue, some of it was very thin, it seemed to him to be best to induce uterine contractions and allow labor to progress slowly so that the parts might dilate gradually.

DR. WARNER further remarked that where the uterus was high up it could be pushed down into the pelvis by the hands of the assistant, and held there firmly while gradual pressure with the finger was made against the os externum.

CANCER OF THE NECK OF THE UTERUS.

DR. TAYLOR narrated a case as follows: In December, 1881, he saw a patient, twenty-eight years of age. Upon examination it was with very great difficulty that he could introduce the finger on account of the resistance offered by the hymen. Finally, he reached a firm, smooth body, and afterward found that the entire posterior portion of the cervix was gone. He diagnosed cancer of the uterus, and decided that the best thing to do was to excise the anterior portion of the cervix, which was exceedingly hard to the touch. No hemorrhage had occurred during the patient's illness, nor was any hemorrhage induced by the examination. Upon making further examination, with reference to operative interference, he discovered that the anterior part of the cervix was ex-

ceedingly vascular, and he decided at once to let it alone, and to await further developments. No hemorrhage occurred, nor discharge, and he did not deem it necessary to make any examination. In the course of a month it became evident that gas escaped from the vagina. There had occurred perforation of the rectum. On account of pain the patient had been obliged to resort to the use of opium, which was gradually increased in quantity until finally she took the equivalent of six or seven hundred drops of laudanum daily; besides, she took a bottle and a half of brandy daily. During all this time the patient's weight and strength rather increased. She died almost instantly from the sudden occurrence of hemorrhage, probably three pints of blood escaping at one gush. At the autopsy the body of the uterus was found to be almost one complete mass of cancerous disease, and the neck was entirely gone. The actual source of the hemorrhage could not be found; that is, no open vessel was discovered. The interest in the case was that it was one of cancer, without hemorrhage or discharge during its progress, and death occurred suddenly in the manner indicated. Dr. Taylor believed that in very many cases of cancer of the uterus it was better to allow the patients to go along under the use of opium and perhaps stimulants rather than resort to operative interference, such as the curette, cauterizing, etc.

DR. WARNER remarked that the only question with regard to the treatment of carcinoma of the uterus was not whether we should curette or resort to any other operative interference, but what benefit is to come to the patient? Does it cure, or prolong life, or lessen suffering? From his own experience in the treatment of carcinoma of the uterus he believed that, as a rule, the plan of interfering surgically rather hastened than retarded the progress of the disease.

DR. TAYLOR believed that in some cases amputation might be followed by beneficial results. He then referred to cases which had been under his observation, and in which the disease had occurred early in life, as early as at the age of from nine to fifteen years, notwithstanding the opinion which had been expressed that carcinoma of the uterus never occurred in virgins.

DR. GRISWOLD referred to a case in which the patient had been operated upon by Dr. Mundé, who removed the entire cervix. He saw the woman two months afterward, and there had been complete reproduction of the growth, and involvement of the vaginal wall. The curette was used, also the scoop, and chloride of zinc was applied, etc., but there was another reproduction of the growth within four weeks. After this nothing was done in the way of operative interference, but the patient was made as comfortable as possible, and she lived for nearly two years. The operation, however, seemed to relieve her from the severe burning pain from which she had suffered.

DR. WARNER asked if it was not a fact that large quantities of alcohol and opium prevented disintegration of tissue. It had seemed to him so in these cases. He doubted very much whether curetting ever arrested the progress of the affection.

EXTRA-UTERINE PREGNANCY.

DR. A. S. HUNTER narrated a case of extra-uterine pregnancy in which the pregnancy had existed apparently not more than three weeks. There was evidence of rupture of the sac, but the patient recovered. He gave the details of the history of the case, which he proposed to make the basis of a paper upon that subject.

DR. WARNER referred to a case in which there was a small tumor in Douglas' cul-de-sac. The woman was forty or fifty years of age, and had never been pregnant. The tumor was somewhat soft, doughy to the feel, and he thought it was a hæmatocele. The uterine sound could be introduced to the depth of five inches. Aspiration removed two ounces of blood, which coagulated im-

mediately. The blood was examined microscopically, and nothing was found which indicated that it came from an old hæmatocele. On the following day another physician was called, who aspirated the tumor as a hæmatocele and drew off twenty-four ounces of blood, which coagulated promptly. The woman died, and the case was reported as one of hæmatocele. The specimen was presented to Dr. Cutler for preservation, and on further examination he found in the cul-de-sac a little foetus. This foetus had probably been there for three or four months.

DR. TAYLOR referred to a specimen of tubal pregnancy which he obtained, and which could be seen in the Wood museum at Bellevue Hospital. The woman had advanced to a little more than eight months in pregnancy when she suddenly fell into collapse and died. It seemed evident that death had been caused by internal hemorrhage, and at the autopsy it was found that the sac was filled with blood, but it had not ruptured.

DR. GRISWOLD referred to a case as follows: About a year ago he was called to see a woman who was believed to be suffering from cholera-morbus. She was not aware that she was pregnant, although she had passed over one menstrual period. She had pain, vomited severely, and had diarrhœa. The patient fell into collapse and died with evidences of internal hemorrhage, and he reported the case as one of internal hemorrhage, probably from rupture of an aneurism. It was made a coroner's case, and upon examination the abdomen was found filled with blood, and closer inspection revealed the presence of a foetus, which indicated that the woman was advanced about eight weeks in pregnancy. The uterus contained a well-marked decidua. The foetus was not found in the Fallopian tube, but the tube when examined gave evidence of the existence of a cyst which had ruptured, and hemorrhage had taken place from the edges of the opening. No distinct blood-vessel could be found which had ruptured.

DR. HUNTER referred to a case of extra-uterine pregnancy which, three years subsequently, was followed by normal pregnancy and delivery of a living child. Not long after the completion of the normal pregnancy the remains of the extra-uterine pregnancy were discharged by the rectum. This was attended by symptoms which indicated purulent infection, and the woman died. In this case, as also in the case which he had already related, the woman when suffering from extra-uterine pregnancy had severe pains, which were remittent in character, and not intermittent. He thought this was characteristic of the pains of extra-uterine pregnancy not infrequently, if not always; particularly in those cases in which rupture of the sac occurred.

The Section then adjourned.

WITH AND WITHOUT ANTISEPSIS.—The statistics of the Surgical Clinic at Basle, in the ten years before and after the introduction of antiseptics, are in interesting contrast.

Thus, of traumatic amputations and exarticulations:

1861-70, 36 cases; mortality, 41.6 per cent.

1871-80, 46 cases; mortality, 15.2 per cent.

Pathological amputations and exarticulations:

1861-70, 28 cases; mortality, 44.4 per cent.

1871-80, 93 cases; mortality, 9.6 per cent.

Internal herniotomies:

1861-70, 36 cases; mortality, 52.7 per cent.

1871-80, 80 cases, mortality, 10.0 per cent.

Complicated fractures of the long bones with primary amputations:

1861-70, 38 cases; mortality, 50.0 per cent.

1871-80, 85 cases; mortality, 12.9 per cent.

Complicated fractures, treated conservatively:

1861-70, 36 cases; mortality, 52.7 per cent.

1871-80, 80 cases; mortality, 10.0 per cent.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE PICRIC ACID CONTROVERSY—THE TESTS FOR ALBUMEN—COLLECTIVE INVESTIGATION OF DISEASE—ANTISEPTIC MIDWIFERY.

LONDON, January 27, 1883.

AN amusing controversy has now been going on for some weeks among prominent medical men, on the subject of urinary tests. The ball was set rolling by Dr. George Johnson who attempted to show that a saturated solution of picric acid was a convenient and reliable test for albumen in urine. Dr. Pavy replied and combated Dr. Johnson's views, recommending, in preference, a saturated solution of potassium ferrocyanide, the urine being freely acidulated by citric acid. Dr. Johnson then returned to the charge, reinforced by his son, an able young chemist, who is a demonstrator of chemistry at King's College. The controversy has lately become somewhat personal. The contemptuous tone assumed by Dr. Pavy toward Mr. G. S. Johnson is scarcely creditable and is not likely to promote good feeling, as Dr. Johnson is not generally believed to be one of the best-tempered men in the profession.

The discussion has had one good result—that of bringing to light several new or modified tests for albumen. Dr. Wm. Roberts recommends a solution of acidulated brine. Mr. Stephen modifies Tannet's test with a standard solution of potassio-mercuric iodide by strongly acidifying the urine with citric instead of acetic acid. Dr. George Oliver has just published a communication in which he recommends the use as reagents of pieces of filtering paper saturated with various test-liquors, then dried, and, when required, dipped in the urine to be tested, which is then boiled. He describes the method as trustworthy, and says that by graduating the papers with standard solutions he has been enabled to make quantitative determinations. I should say that besides employing picric acid as a test for albumen, Dr. Johnson has also employed it as one for sugar.

The event of last week was the large meeting of the Metropolitan Counties Branch of the British Medical Association, convened at the Royal School of Mines to consider the subject of the "Collective Investigation of Disease." Addresses were delivered by Sir William Gill and Sir James Paget. The powerful advocacy of two such distinguished men can scarcely fail to stimulate a movement which has already attained some not inconsiderable success. The replies already received would seem to indicate that not only the hospital staffs of London and the large towns but many general practitioners throughout the country are disposed to assist in advancing the scientific study of disease. Organized by a central committee and working on definite lines the profession may reasonably expect great results from their united labors.

Antiseptic midwifery is receiving a fair trial at the British Lying-in Hospital. A little information as to the methods in use, derived from personal visits to the hospital, may interest your readers.

Antiseptics are now employed in every case. Previous to fresh patients being received into a ward it is washed out with a solution of carbolic acid, disinfected by burning sulphur in it, and then left with the windows open for several days. A long-spouted kettle containing an aqueous solution of carbolic acid (one in twenty) stands on a table in the centre of every ward. This is heated by a small jet of gas and, being always kept going, the atmosphere of the wards is kept constantly impregnated with carbolized spray. Carbolized oil is used by the midwives and nurses to anoint the fingers before making digital examinations. The patients are delivered under a cloud of carbolic spray (one in twenty solution), which is kept playing

on the vulva during labour. A steam spray is usually employed, but a hand-ball spray with three jets is always kept in readiness besides, for use when the steam spray is not ready, so that the spray is never omitted in any case. Dr. Fancourt Barnes thinks that this prevents the entrance of any germs into the uterus at the moment when the vagina is dilated by the passage of the child. He gives a quinine, opium, and ergot mixture for the first few days after delivery to keep the uterus contracted and thus prevent any germs from entering. The vagina is syringed out daily for the first ten days after delivery with a (one in sixty) solution of carbolic acid. All washings of the genitals are performed with carbolic solution (one in eighty). These antiseptic measures have been used at the British Lying-in Hospital for about two years, and since they have been in vogue no deaths from puerperal fever have occurred, and during the past two years (1881 and 1882) only two deaths from any cause whatever among three hundred and thirty-two women delivered. Febrile temperatures after delivery, which were formerly common, are now quite the exception. It should be noted that in addition to these antiseptic procedures, so called, *the strictest cleanliness is observed*. The tables and chairs, etc., in the wards are painted *all over*, and when washed are thoroughly washed *all over*, so that no hiding-place for dirt is left anywhere. Ample provision for ventilation is made by means of open fireplaces, cross windows, inlet openings on Tobin's plan with wire screens (which can be washed out periodically) under the windows, and outlets in the ceiling, which communicate with an exhaust shaft. Each ward only contains four beds, and is large and lofty. There is a separate labour ward. The mattresses are disinfected from time to time by being baked in a hot oven. During the month of August in every year the hospital is closed and thoroughly cleaned throughout, and the walls limewashed afresh.

CONVALLARIA MAIALIS—A POWERFUL POISON TO ANIMALS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I have read with the greatest interest the clinical experience of Dr. Henry Ling Taylor with the new cardiac tonic—convallaria maialis. One caution only seems necessary. From experiments on animals, it is proved that convallaria is a powerful toxic agent, not inferior to digitalis in its power to cause speedy death. Therefore, in its clinical application to human patients it is well to be a little careful about the dose prescribed. I am surprised at the largeness of the dose given in some of Dr. Taylor's cases, *i.e.*, one ounce of Parke, Davis & Co.'s fluid extract. It would never do to give this as a commencing dose.

I have made some experiments on animals to determine the poisonous effects of convallaria. The preparation used—the only reliable preparation now in the market—was Parke, Davis & Co.'s fluid extract. I shall not burden you with the details of all these experiments. I am a very crude experimenter, and my experiments all lack precision. I shall therefore copy from my note book memoranda of only three or four:

September 16, 1882.—Poisoned a four weeks kitten with fluid extract convallaria; ten drops Parke & Davis's fluid extract under skin of back. Tremblings; hurried respiration; staggering. These convulsions and death in fifteen minutes from the reception of the poison. Necropsy showed heart arrested in systole, both ventricles empty and firmly contracted.

October 3d.—A four months kitten, plump and healthy. Fifteen minims convallaria under skin of back. Kitten lay stupefied fourteen minutes, rapid respiration and circulation, then went into convulsions, first clonic, then tonic, and died with screams. Heart ventricles empty and firmly contracted.

Other experiments on kittens are so similar that a detailed account is not necessary.

Five minims under the skin of a frog's back arrested the heart's action in less than twenty minutes. Professor Sée says: "The phenomena are identical in the same conditions in cold-blooded animals, but the heart of the frog and turtle resist longer the action of the drug."

Convallaria, then, is a cardiac poison which arrests the heart in systole like digitalis. In several experiments on kittens which I have poisoned with digitalis, and in which I injected under the skin from ten to fifteen minims of the tincture, death took place in about a quarter of an hour, but *without convulsions*, complete stupefaction and paralysis of all the vital functions being the marked phenomena.

In some of Professor Sée's recorded experiments with convallaria, he found *four drops* of a fluid extract cause the death of medium-sized dogs in *ten minutes*. From a private letter from Dr. H. L. Taylor, dated February 3d, I quote the following sentence, which shall be my justification for citing these few imperfect experiments—especially imperfect because I did not ascertain the minimum dose which would cause death, as well as the weight of the animals experimented on: "I am afraid that incautious men may do damage to their patients and to the reputation of the drug by beginning with large doses in susceptible persons unless the toxic power of the drug is known. My article failed to bring this out."

E. P. HURD, M.D.

NEWBURYPORT, MASS.

TRANSPLANTATION OF THE CONJUNCTIVA OF A RABBIT.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: On page 42 of THE MEDICAL RECORD of January 13th ult., a brief editorial transcribes an interesting case in the Jefferson Medical College Hospital, Philadelphia, where, for the relief of cicatrization of the lids to the eyeball, a rabbit's conjunctiva had been grafted in lieu of the one destroyed. The case seems to have been unusually severe, as the right eye was entirely destroyed, and the left, as stated, was ankylosed to both lids. This operation of transplantation of the major part of a rabbit's conjunctiva has been rarely performed, probably on account of its tediousness and indifferent success. It is not as recent a procedure as might be supposed. Wolfe, of Glasgow, an authority in plastic operations within and without the lids, claims to have made the first transplantation in 1872, again in 1873, and has been followed by Wecker, Becker, Cohn, Schoeler, and others. Wolfe's description in "Diseases and Injuries of the Eye," 1882, details the questions of narcosis of the rabbit and patient, one or both, the method of transfer of the flap, and his own success. He mentions one of the elements of failure, viz., the facility with which the edges and corners of the delicate flap roll forward. He omits to mention the difficulty of keeping the flap in the inferior cul-de-sac, which may be overcome by stitching it at intervals down through the whole lower lid. In the spring of 1876 the writer assisted Schoeler and Sellerbeck, at the eye clinic of the former in Berlin, in several transplantations from the rabbit where the loss of human conjunctiva had been large. The success of these operations was mediocre. It is interesting to note that in gynecology the mucous membranes of the rabbit have been successfully transplanted. In this connection, attention might be called to the ingenious operation devised for improvement of sight in eyes with dense opacity of the cornea, almost total blindness, and a consignment of the patient to a life of helplessness. Schoeler practised it early in 1876 with large success in several cases. In brief, the conjunctiva of the patient was dissected in two parallel lines from the inner canthus to the periphery of the cornea, was reflected over the latter so that the external surfaces of both tissues were *enface*, and the tail of the rhomboid flap was stitched to the outer conjunctiva. The gap at the inner canthus was then filled with rabbit's

conjunctiva. The two epithelial surfaces united, while the remainder of the reflected conjunctiva sloughed away. Finally, the cornea has been transplanted in section with success, an operation attempted nearly fifty years ago, and which, in 1839, attracted the attention of the University of Munich.

EDWARD S. PECK, M.D.

NEW YORK.

Army News.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from February 3, 1883, to February 10, 1883.

DE LOFFRE, AUGUSTUS A., Captain and Assistant Surgeon. Will be relieved from duty in the Department of the Missouri and report in person to the Commanding General, Department of the East, for assignment to duty. S. O. 26, par. 3, A. G. O., January 31, 1883.

ELBREV, FREDERICK W., Captain and Assistant Surgeon. The leave of absence on Surgeon's certificate of disability, granted July 21, 1882, is extended six months. S. O. 26, par. 5, A. G. O., January 31, 1883.

TAYLOR, B. D., Captain and Assistant Surgeon. Granted leave of absence for one month, on Surgeon's certificate of disability. S. O. 13, par. 2, Department of Texas, February 1, 1883.

TAYLOR, MARCUS E., Captain and Assistant Surgeon. So much of S. O. 20, A. G. O., January 24, 1883, as directs him to report in person to the Commanding General, Department of the East, is amended to direct him to report in person to the Commanding Officer, David's Island, New York Harbor, for duty at that station. S. O. 33, par. 2, A. G. O., February 8, 1883.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Comparative statement of cases of contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending February 10, 1883:

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
February 3, 1883.....	2	10	59	1	92	44	0	0
February 10, 1883	0	4	69	6	73	41	0	0

A SANITARY CONVENTION was held at Pontiac, Mich., January 31st and February 1st, under the auspices of the State Board of Health.

THE ONTARIO LEGISLATURE will probably contain three doctors, and the Dominion Senate two.

INOCULATION OF MONKEYS WITH SYPHILIS.—Dr. Martineau, of the Lourcine Hospital, claims to have at last inoculated a male monkey with syphilis. A typical chancre is said to have appeared on the penis twenty-eight days after the inoculation. The virus is being tested upon other monkeys.

THE DUBLIN HOSPITAL SUNDAY FUND.—The last collection amounted to about twenty thousand dollars.

BLACK SOAP.—Several of our correspondents ask what is the composition of *black soap* mentioned in connection with Kern's cataplasmata for the treatment of malignant lympho-sarcoma. Will any of our readers answer?

AT AN ANTI-VACCINATION MEETING recently held in Edinburgh, it was claimed that thirty thousand names had been obtained to a petition against vaccination, and that Edinburgh University had lost \$60,000 in consequence of Dr. Rutherford's experiments. There is probably some exaggeration in the statements.

THE GELATINE URETHRAL BOUGIES.—Dr. Robert Newman, of this city, calls our attention to an error in the report of his remarks made before the State Society concerning the use of the gelatine urethral bougies. He wishes it to be understood that these bougies should never be used when their introduction causes pain, the latter being the case when the canal is in a high grade of inflammation. Under all other circumstances they can be employed with impunity.

DIPHTHERIA FROM INFECTED MILK.—Drs. Cameron and Morell Mackenzie have recently traced a severe and sudden epidemic of diphtheria to infected milk. Fifteen persons were attacked in the same day. The milk vendor was found to have washed his cans in a brook polluted with sewage.

HYOSCYAMIN AND HYOSCYAMINE.—Hyoscyamia or hyoscyamine, of which the dose is one-sixtieth of a grain, is the true alkaloid of hyoscyamus, being analogous to atropia or atropine, which is the alkaloid of belladonna. But for years there has been in the market a preparation of variable strength, stronger than the extract, but much weaker than the true alkaloid; and this preparation is called hyoscyamin. Of this preparation one-eighth to one grain may be given. The only distinction between these two names, when properly written, is in the final letter "e" being added to the name of the true alkaloid; but what shall we say when, on turning to the United States Dispensatory for 1878, we find the terms used synonymously? The cautious physician who is acquainted with these facts will beware how he prescribes hyoscyamin, unless he has thorough confidence in his druggist.—DR. C. F. CLARK, *Therapeutic Gazette*, January, 1883.

THE INFLUENCE OF SULPHUROUS ACID IN ARRESTING PHTHISIS.—Herr Kircher, a pupil of Liebig, has been, during forty-four years, director of an ultramarine factory, in which a special process of manufacture is employed which involves the formation of sulphurous acid by the burning of sulphur. He maintains (according to the *Gesundheit*) that none of his work-people have ever suffered from consumption, typhus, cholera, or any disorder, which is produced by bacteria. He recommends the following treatment in the case of tuberculous patients. They should be brought into a room in which small quantities of sulphur (one to two drachms) are burnt every hour over a spirit-lamp or on a stove. At first coughing of a more or less aggravated character takes place, and after eight or twelve days the bacteria gradually disappear and cease to irritate the lung-tissue. To complete the cure, the patients should be brought into rooms which contain some aromatic vapors.—*The Lancet*.

THE ANÆSTHETIC ACTION OF STYRONE.—Dr. S. A. Popoff has made experiments with styrene, a substance first described by Dr. Beach (*Boston Medical and Surgical Journal*, July, 1880), and obtained from storax and balsam of Peru. Aside from its powerful antiseptic properties, he found the following in experimenting upon frogs and dogs. 1. Hypodermic injections of one milligramme in frogs caused complete anæsthesia dependent on paralysis of sensory nerves. 2. A large dose caused convulsions followed by motor paralysis. 3. The intravenous injection of five to eight centigrammes per kilogramme of weight in dogs caused also anæsthesia. The drug was found to depress the respiratory centre and at times the temperature.—*Mediz. Obozr.*, February, 1882.

THE SEDATIVE ACTION OF STIGMATA OF MAIZE.—M. Ducasse has recently experimented largely with the extract of this drug, and finds it to have a specially sedative

action on the genito-urinary tract. In the dose of twenty-two grains he finds that the extract has a calming influence on the pain of chronic cystitis, gravel, and nephritic colic, at the same time aiding in the expulsion of gravel. This anæsthetic action is very marked, especially in nephritic colic, where it calms the pain when morphine injections have proven ineffectual; its action is followed by micturition, the urine carrying away with it a large proportion of gravel. If the medicament be continued for a time, the accidents rarely return. It is, in fine, he claims, the best preventive of gravel and of nephritic colic.—*Philadelphia Medical and Surgical Reporter*, January 20, 1883.

ICHTHYOL IN THE TREATMENT OF ARTICULAR AND MUSCULAR RHEUMATISM.—Dr. Rudolf Schröter, of Hamburg, has discovered a peculiar oily compound, which he calls ichthyol. It is obtained from a bituminous substance found in certain fossiliferous rocks. This is distilled and treated with sulphuric acid. Dr. P. G. Unna states that its action in acute and chronic articular and muscular rheumatism is astonishing. Several of his colleagues report similar results. Ichthyol has been used chiefly in skin diseases, psoriasis, etc.—*Monatshefte f. Praktische Dermat.*, December, 1882.

THE SUCCESSFUL QUACK.—In the *Therapeutic Gazette*, December, 1882, Dr. Neiller, of Kansas, draws an amusing picture, apparently from nature, of a successful quack:

This individual changed teams, and even conveyances, three or four times daily, driving into town with break-neck speed one moment, with a match of grays and a buck-board wagon, and going out the next with a bay and a black and a top carriage. He never came nor went by the same avenue twice the same day, but always selected different portions of the town to pass through, so all could see him, and those who had forgotten him one day would not be left in oblivion of him the next. His horses and carriage were always found waiting for him at his office, down town, every Sunday morning about 10 o'clock, so that people going to church, especially country people, would not miss this opportunity of being reminded of him once again. They were found there on Saturdays, off and on, all day long; they were there upon all public occasions when there was the least or the greatest chance of displaying them. Although always before the public eye, either in whirling around town or in scouring the country over, he never missed a call to my knowledge, and could always readily be found when wanted. He never walked a step, being driven even in his visits about town, an ordinary country town, though the distance was but the half of a block. He subscribed to all charities, public and private; he belonged to all the orders, associations, societies, fellowships and leagues in the town and county; his mail was an immense one, nightly, of medical journals, newspapers, pamphlets, letters, books and circulars, which he never read, but which were conspicuously displayed, by the armful; he supported the widow and the destitute, having the donations conveyed by the broadest avenues; his house was ever open to the lame, the blind, and the halt, simulating, in a manner, a hospital, on a small scale, and he who once entered his portals never departed therefrom but with an exalted opinion of its owner. This was not only the case in regard to the stranger, but was also a studied point with the neighbors, friends and patrons, with all those who had any occasion to enter his doors, where they were taken in charge by the "better half" and given a thorough course of training. To enter but once was certain oblivion to all other gods but the little god brought forward for display, and all the cunning of a singularly crafty nature was brought to bear upon this one point.

His fees were always less than the ordinary fees for the services rendered, from an inherent feeling of justice; they were never collected but by routes entirely foreign

and circuitous; they were "charmed" from his patrons in a manner not well understood themselves. He had a well paid clique constantly surrounding him, who were ever filling the community with the records of his skill and good deeds; he felt so much at peace with his own dear little self and all the world that he could not help but show it in his face, in his arms and in his swagger; his office was a perfect little curiosity shop of instruments, appliances, devices, chromos, crayons (by his wife), oil paintings (also by his wife), and medical anomalies. Five years of this kind of quackery had built him up such an extensive practice and had woven such a web of popular fanaticism about him that it were next to impossible to break down.

THE CORSICAN BROTHERS AND MIND-READING.—The powerful melodrama of the "Corsican Brothers," recently played in this city, originated from a supposed case of mind-reading. The story, as told in "Men of the Time," is as follows: "As Louis Blanc was returning home one evening in October, 1839, he was suddenly assailed from behind by some ruffian, who inflicted a violent blow with a stick on his right eye. The author of this cowardly attempt—which was made the day after M. Louis Blanc had published a review of Louis Bonaparte's work, 'Les Idées Napoléoniennes'—was never discovered. M. Louis Blanc had a brother one year younger than himself, who was at that time at Rodez, in the department of l'Aveyron, and who entertained so strong a conviction that his brother was being assaulted at the precise moment when it really occurred that he was induced to write at once for information to Paris. This incident was the origin of M. Dumas' 'Corsican Brothers,' the main subject of which is the preternatural sympathy between two brothers." It may be mentioned that the death of Louis Blanc followed that of his brother with very little interval.

QUACKERY IN LONDON.—Apropos of the remarks in the *Medical Press and Circular*, characterizing New York and the "States" generally as terribly quack-ridden, we quote the following from the *Journal of Science*. It shows that things occur in London which would not be possible in many parts of America: "A quack who has his headquarters near Westminster Bridge has an ingenious method of beguiling the public. He tells his hearers that if a person affected with incipient consumption blows through a glass tube into water it will at once turn milky, and invites them to make the trial. As the liquid which he offers is lime-water, the result follows as a matter of course. He then adds a few drops of his medicine (containing some acid) to the water, when the cloudiness at once disappears. This he argues is a proof that the same remedy will eradicate consumption from the human system. Multitudes of those present believe him, and buy his secret remedy."

A SOUND IN THE OESOPHAGUS FOR THREE HUNDRED AND FIVE DAYS.—Krishaber reports a case of malignant disease of the oesophagus with stricture. In order to keep the passage open, an oesophageal tube was introduced and allowed to remain. The outer end was carried through the nose and attached to the forehead. After a time tolerance was obtained and the instrument was kept in until death occurred.—*Deutsch Med. Woch.*

THE SALTS OF NICKEL are claimed to be excellent and powerful disinfectants. Dr. Hugo Schulz, who has studied their action, uses the chloride, and finds that even one-tenth of one per cent. solutions will kill bacteria *termo*.

A NEW HYPNOTIC AND DEPRESSO-MOTOR.—Herr Schiffer, of Berlin, has recently been studying the action of guachamacá, a Venezuelan plant. It acts very much like curare, in allaying spasm, and in large doses causing a general paresis. The juice taken from the plant in the rainy season makes the most powerful preparation. If ten milligrammes of the extract are given to a frog, an interval

of fifteen to eighteen minutes passes before any effect is noticed. After this period, however, the action is rapid. The animal becomes stupid, allows the head to fall, permits itself to be laid on its back, and does not draw back the leg if extended, etc. So far its action is exactly similar to that of curare; but now comes the difference. The respiration continues, the circulation and cardiac activity are undisturbed. Its effect was tried on a young man in Frerich's clinic who was suffering from cramps. Ten milligrammes of the extract were injected, but for three-quarters of an hour no effect was observed. The patient then, in broad daylight, suddenly fell into a rather deep sleep, which lasted for nearly three hours; respiration and circulation were undisturbed. Schiffer believes that in guachamacá we have an agent capable of combating disorder of the motory apparatus, as well as a useful hypnotic.

MARWOOD'S DROPS.—Mr. Marwood, the London hangman, being asked by a neighbor what was a good remedy for a troublesome cough, is reported to have replied that his "Marwood's Drops" had never yet been known to fail.

SUICIDES IN PHILADELPHIA.—There were 89 suicides in Philadelphia last year. This is more than in 1880, when the number was 68. New York as usual is far ahead of her neighbor: in 1880, 152 persons killed themselves, making a ratio of 12.59 per 100,000, while Philadelphia had a ratio of 8.03 per 100,000. Boston has a ratio of 11.03 and San Francisco of 37.65 per 100,000.

A PRIOR CLAIMANT TO GALVANI'S DISCOVERY.—Professor S. Thompson points out the little-known fact that Swammerdam anticipated the famous initial experiment of Galvani by more than a hundred years. Being on a visit in Tuscany, in 1678, the illustrious Dutch naturalist showed to the Grand Duke that when a portion of muscle of a frog's leg, hanging by a thread of nerve bound with silver wire, was held over a copper support so that both nerve and wire touched the copper, the muscle immediately contracted.

THE IMMIGRANT AND SMALL-POX.—Dr. P. H. B., of Washington, D. C., writes: "Referring to an excellent article in THE RECORD of January 6, 1883, entitled 'The Immigrant and Small-pox,' I am of opinion that the efforts of the Health Officer of your port, Dr. W. M. Smith, are being made in the right direction. He stated in my hearing that he had long ago instituted a measure which, if properly carried out at other ports, would obviate all necessity for an 'Immigrant Inspection Service' within the interior of the United States. His plan had been to require the inspection and vaccination of immigrants to take place on the other side of the water, or in case that was not done, to be completed on shipboard within three days from the time of the vessel leaving a foreign port. He stated that he had issued many circulars and cards to this effect, explaining thereon that by such inspection and vaccination, immigrants would be saved from detention upon their arrival at quarantine in New York. He thought that similar measures adopted at other ports with a penalty or fine for non-compliance would result in immediate benefit, and that ultimately steamship companies would find it to their advantage to transport no immigrant who was likely to get them in trouble either by delaying them in quarantine or causing them other expense.

"I would supplement these suggestions of Dr. Smith by adding that if ships were made liable for all expenses incurred in the care and treatment of all immigrants infected with small-pox or other contagious disease landed by them, or who are taken sick with any contagious disease within ten days after landing such immigrant, the necessity for inspection by the United States Government would not only be obviated, but the importation of disease would be greatly decreased and local quarantine establishments less cumbersome and expensive."

Original Lectures.

ON THE RELATIONS OF MICRO-ORGANISMS TO DISEASE.

THE CARTWRIGHT LECTURES, DELIVERED BEFORE THE
ALUMNI ASSOCIATION OF THE COLLEGE OF PHYSICIANS
AND SURGEONS, NEW YORK.

By WILLIAM T. BELFIELD, M.D.,

LECTURER ON PATHOLOGY, AND ON GENITO-URINARY DISEASES (POST-GRADUATE
COURSE), RUSH MEDICAL COLLEGE, CHICAGO.

LECTURE I.¹

Mr. President and Gentlemen: In accepting your flattering invitation to deliver the Cartwright lectures, I have, in compliance with your request, selected my present subject—almost the only one indeed which I would venture to discuss in your presence—not simply because of its intrinsic importance and interest, but also because there exists in the medical public of our land a diversity of opinion concerning it, which is not, in my estimation, warranted by the facts. For since trustworthy original investigations in this direction, demanding continuous devotion of the observer to the subject and the renunciation of other pursuits; demanding special training and experience; requiring laboratory and other expensive facilities; since such investigations, possible therefore in general only through State or corporate assistance, have been, and under existing circumstances must be made almost exclusively in other lands than ours; since, further, important results attained within recent years and published in foreign tongues have been as yet but partially incorporated in our standard literature; since the tendency of the practising physician—to which category we all, with rare exceptions, of necessity belong—is ever toward the cultivation of the art rather than the science of medicine; since, finally, there is a prevalent disposition to ignore the entire subject as trivial or fanciful; for these, and perhaps other reasons, there prevail, as it appears to me, some misconceptions as to the present state of knowledge on this subject. It shall be, accordingly, my effort to present in these lectures no original investigations, no theories nor views, but simply the facts already established, and the deductions incident thereto—an effort which I am encouraged to undertake by some familiarity with pertinent literature, and by some little practical knowledge of the methods and manipulations involved.

In order to discuss intelligibly the more recent and familiar subjects, such as the rôle of the bacillus tuberculosis, we must bear in mind certain facts, less sensational and perhaps less widely known, concerning the life-history of microscopic parasites.

Although even the early microscopists, beginning with Leeuwenhoek (1675), observed and studied bacteria; although these minute bodies were observed in animals dead of septic infection by Fuchs, in 1848, and in the blood of sheep dead of anthrax by Brauell and Davaine, in 1849 and 1850, no effort appears to have been made to establish a genetic relation between the plants and the disease until the publication of Pasteur's work on fermentations, in 1861. Then the bacteria which had been

the unenvied monopoly of biologists suddenly acquired deep interest for pathologists. The experimental work on septic infection, by Mayerhofer, Coze and Feltz, Rindfleisch, Wokleyer, and Recklinghausen, in 1865, 1866, and 1867, drew the attention of the medical public to the subject. Meanwhile Lister, impressed with the results of Pasteur's work, and desperate (as I was informed by a Glasgow neighbor of his) at the death from pyæmia of several cases in rapid succession, anticipating the tedious progress of experimental science, submitted the question to empiric arbitration on the operating table. His clinical results revolutionized surgical methods on the one hand and infused new vigor into experimental pathologists on the other; the number of workers and of works so rapidly increased that to-day simple mention of the literature of this subject would be the work of hours. I deem it, therefore, inexpedient to attempt, in the limited time at my disposal, a historical sketch of the development of the question, and shall endeavor to present merely the present knowledge of the subject, with a review of the evidence upon which it rests.

Many of the elongated bacteria have been demonstrated to possess also a thread-like projection from the extremity, a flagellum or cilium; these, as well as some other varieties not yet proven to possess flagella, are capable of independent, often rapid locomotion in liquids; others are devoid of flagella, and incapable of motion; hence it is highly probable that the power of locomotion is associated with the possession of cilia. Beyond this bacteria seem to possess no differentiation of structure nor localization of function; nutrition and assimilation are processes of osmosis. This simplicity of structure and function has given rise to discussion as to whether they should be regarded as animals or vegetables; the question is, of course, merely a technical one of classification; since the features which distinguish the higher animals from the higher plants disappear as we descend the scale of organic life until few or none remain; yet because almost all of the simplest organisms hitherto called animals, the flagellata, possess a rudimentary mouth and are capable of absorbing solid food, while the simplest plants are not so characterized, the bacteria have been assigned to the vegetable kingdom. Whether they should be called algæ or fungi is a question for botanists to decide; the power of independent motion exhibited by some varieties suggests affinity with the algæ; but the absence of chlorophyll is generally considered to require their classification among the fungi.

The necessities of their existence are as simple as those of the mould fungi; indeed, so nearly identical as to require no discussion. As to the chemical reactions incident to their vital activity, our present knowledge is very scanty; one variety is known to induce the transformation of grape and milk sugar into lactic acid; another the decomposition of glucose or lactic acid with formation of butyric acid; another the change of urea into carbonate of ammonia; some produce pigments, blue, red, yellow; of many we know only that they transform a solid substance—gelatine, for example—into a liquid; but one of the most important facts in regard to them is the proof that putrefaction of albuminous substances is a phenomenon incident to the vital activity of certain varieties—the bacterium termo and probably others—as must be admitted by every one familiar with the work of Pasteur, Tyndall, and their pupils. Until the chemistry of their vital processes is ascertained, it will be impossible to as-

sert how they can be injurious to a living tissue, whether by simple mechanical irritation, by the appropriation of oxygen and other nutritious elements, by the excretion of substances injurious to animal cells, or in several of these ways combined. The formation of substances incompatible with the life of the animal cells seems to play a prominent rôle in the production of injurious effects by at least some varieties.

The simplicity of organization and vital requirements explains their extensive distribution in nature: every moist substance of organic origin and all water containing even a trace of organic matter is favorable soil for one or more varieties; the upper layers of the earth, containing these essential ingredients, and remaining comparatively warm, constitute a continual breeding-place for these organisms. The minuteness and lightness of bacteria explain their presence in the atmosphere; they are swept by currents of air from dry or moist surfaces; they float in clouds of dust; they are carried by insects; the persistence of their vitality, the rapidity of their propagation, result in practical ubiquity. Direct microscopic observation of atmospheric dust, and the experiments of Tyndall with the electric beam in a dark chamber, have shown that wherever we find dust, at moderate temperature and altitude, we may expect to find bacteria. Yet the atmospheric bacteria are probably not so numerous as has been pictured. The observations of Miquel and of Koch show that even in a laboratory many litres of air contain no organisms. Whether or not bacteria are swept from surfaces of liquids; whether after once drying upon a given surface they can be removed by air-currents, are as yet undecided questions which may have practical bearings in the future. At present we know no laws of atmospheric distribution wherein bacteria exhibit other behavior than particles of dust in general.

The champions of spontaneous generation, compelled to surrender their maggots in decaying meat to the simple demonstration that covering the meat with fine gauze, which prevented the access of flies, prevented also the development of maggots; forced to abandon intestinal worms by the successive demonstrations of numerous observers that each worm proceeded, though often by devious ways, from a similar pre-existing organism, found a tower of strength in the bacteria, a position fortified by a series of careful, conscientious, and delicate experiments by Bastian and Pouquet. The result of that contest is known to all. The errors in manipulation and interpretation upon which the proof of spontaneous generation rested were detected, and a series of hitherto unassailable experiments by Pasteur, Tyndall, Traube, and Brefeld compelled the admission that bacteria, like the intestinal worms and the maggots, and all other living things, illustrate the dogma, "*omne vivum ex ovo*." Yet this phantasy of spontaneous generation seems a spook which can never be exorcised from man's imagination. Quite recently Arndt has deduced from experiments, to which I shall presently refer, a conclusion which may be regarded as modified spontaneous generation; namely, that certain elements of animal-cells can, under favoring conditions, continue to exist and develop into bacteria after the death of the cells of which they were previously constituent molecules. Yet the evidence adduced does not as yet warrant any hesitation in accepting the current doctrine that bacteria, like all other organisms, proceed from pre-existent similar beings.

In order to discuss intelligibly the individual bacteria, we must agree upon a classification. The nomenclature has given rise to much discussion and more confusion. At first each investigator christened, after his own fancy, every new variety. The French school, first in the field by virtue of Pasteur's work on fermentation, employed, very loosely, the terms vibrios, monads, torulaceae, etc. Natural selection has proven Cohn's classification the fittest to survive, which is quite natural,

since the greater part of our exact knowledge of this subject is due to this distinguished botanist and his pupils. Cohn's original classification permits and will doubtless need amendments; in fact, he has already proposed some essential modifications based chiefly upon the form and mode of association of the individual cells. I shall adhere to that nomenclature in general use by the German mycologists.

FIG. 1.—Various bacterial forms. 1. *Micrococcus septicus*; 2, scattered; 6, in chains—torula. 2. Same in zoöglœa form. 3. *Bacterium termo*. 4. Same in zoöglœa. 5. *Bact. lineola*. 6. *Bacillus subtilis*. 7. *Bacillus anthracis* and blood-corpules. 8. *Bacillus* (from mouth) with cilium. 9. *Bacillus lepræ*. 10. Bacilli with spores. 11. *Bacillus malarie*. 12. *Vibrio serpens*. 13. *Spirochete Obermeieri*. 14. *Spirillum volutans*. 15. *Sarcina*. X 500. (Copied from Ziegler's path. Anatomie, Jena, 1882.)

Bacteria are distinguished in this system according to form simply into (1) micrococci, or sphaerobacteria; (2) microbacteria, or simply bacteria; (3) bacilli, or rod bacteria; (4) spirilla, or spiral bacteria. A disadvantage in this nomenclature is the employment of the word bacteria to designate two different conceptions—the entire tribe including all four classes, a general name, and the second class, microbacteria, in distinction from the others—a double signification which has led to some confusion. The micrococci are the smallest, and, hence, individually least perfectly known; so small, indeed, often less than one micromillimetre in diameter, that nothing definite as to structure and contents has, as yet, been ascertained. They seem to exhibit in general no independent motion; they occur either isolated, in pairs, in chains (*streptococcus* or *torula*), or, when multiplying rapidly, in large numbers imbedded in a gelatinous material produced by the organism—the whole mass being termed zoöglœa. Some are colorless, others pigmented.

Of the bacilli, Cohn makes two genera—*bacillus* and *vibrio*; others add more varieties. The members of the genus *bacillus* are cylindrical rods; they multiply by fission, and some certainly exhibit a second mode of reproduction—the formation within their sheath of minute globular or ovoid bodies, spores, which subsequently escape by rupture of the sheath, and are capable, under proper conditions, of growing again into the rod form. These spores exhibit a tenacity of life not possessed by the mature bacilli, nor indeed by other varieties of bacteria, since their vital activity is sometimes unimpaired by prolonged boiling, or by immersion for months in absolute alcohol, either of which procedures destroys mature forms. The spores seem under ordinary conditions the impersonations of immortality: time seems powerless to weaken them.

In order to study the phenomena accompanying the presence of bacteria in animal tissues, one must naturally first identify the bacteria. Now this is a more serious undertaking than the current literature on the subject in our language would imply. A bacterium is a mass of matter which possesses a definite size and shape, may or may not exhibit motion, has a certain chemical composition, and is capable of growth and reproduction—is, in short, a living organism; and no mass of matter can be justly called a bacterium until proven to possess these several characteristics; for one or more of these several properties may be exhibited by bodies found in the animal tissues which are not bacteria.

An unfortunately large number of publications on this subject exhibit by negative inference or positive demonstration, a failure to appreciate this self-evident fact. Size, shape, and, above all, movement, are considered conclusive evidence of bacterial nature. Size, shape, and presence or absence of motion may be determined by direct observation under the microscope; distinctive chemical traits may be detected by behavior toward certain reagents; the various aniline colors distinguish at once the protoplasm of bacteria from cell-bodies, fibrin threads, fat-granules, crystals; for every known bacterium absorbs one or more of the aniline dyes in watery or alcoholic solution. Yet size, shape, motion, and absorption of aniline dyes do not conclusively prove the bacterial nature of the body under examination, since the same phenomena may be exhibited by material forms which are not bacteria. Micrococci cannot thus be individually distinguished from the granules found in the nuclei of many cells, in leucocytes, and floating free in the blood; rod bacteria are sometimes closely simulated in size and shape by fibrin threads and organic crystals. Groups of bacteria, especially of the micrococcus tribe, are simulated by nuclear detritus floating in the blood, as pointed out by Riess; by large granular cells, the "Mastzellen" of Ehrlich, which are found in large numbers in various inflamed tissues, in diphtheria, typhoid fever, elephantiasis Græcorum, for example; by cross-sections of fibrin threads in blood-vessels; by globular masses usually considered to be leucine, which may occur, apparently, in any tissue, in normal as well as in certain pathological states. It is true that experience teaches one to distinguish these bodies from bacteria, in some cases, by their appearance and reaction to staining agents. Yet absolute certainty can usually be secured, even by the experienced mycologist, only by cultivation outside of the body. In the independent exhibition of reproductive power, by fission or spore formation, or both, lies, therefore, the only positive proof that a particle under examination, exhibiting the size, shape, and reaction to staining agents characteristic of a bacterium, is actually one of these lowly organisms, and not an unorganized mass of similar appearance.

The theoretical considerations end here, but the practical difficulties begin; for, in order to be sure that an organism which grows in a liquid outside of the body is the same as the particle previously observed within the tissue, we must be assured that no other organism can have obtained access to the culture fluid; for the microscopic dimensions of the particle prevent continuous observation during the transfer, and the morphological similarity of different varieties, especially among the micrococci, render individual recognition impossible. Every object which can come into contact with the liquid or the particle under examination—the skin of the animal from which the tissue is transferred, the instruments, the vessel or slide containing the nutrient material, the material itself, the surrounding air, so far as possible—must be sterilized, liberated from all contained and adherent organisms; and even then there remains an element of uncertainty, since it is impossible (by the ordinary methods of cultivation) to demonstrate that these precautions have been efficient. These difficulties of sterilization cannot be fully appreciated without actual experience, which soon demonstrates that the greatest care and attention is often impotent to secure the isolation of a given species from other bacteria; Bastian's famous experiments in support of spontaneous generation may serve as an illustration.

In his earlier work, though carefully and conscientiously performed, the apparently spontaneous appearance of bacteria in various animal and vegetable infusions was easily explained by his failure to previously heat the glass vessels in which the infusions were kept; for the observance of this now elementary precaution prevented the appearance of organisms in the liquids. But later experiments seemed indeed unassailable; he

found that thoroughly boiled urine remained, in a previously heated and well-stoppered flask, perfectly free from organisms; when, however, the urine was made alkaline by the addition of a caustic potash solution, also previously boiled, the conditions remaining otherwise unchanged, bacteria were soon developed in immense numbers. Bastian explained by the hypothesis that alkaline was more favorable than acid urine to the generation of these organisms. Pasteur, skeptical as to the accuracy of Bastian's manipulations, repeated the experiment and secured the same result—bacteria were developed, even with the greatest possible attention to details of execution. He found, however, that if the caustic potash were added to the urine, not in watery solution but in the pure state after heating to redness, no organisms were developed; further, that if Bastian's solution of caustic potash and urine were heated to 110° C., no development of life occurred. The error was therefore the assumption that all organisms in the potash solution, as well as in the urine, were destroyed by boiling—an assumption now known to be at variance with the fact. Tyndall also narrates an instance which would have been in less careful hands misinterpreted. He removed from a clear, sterilized infusion a drop of liquid, and to his astonishment found it, under the microscope, swarming with bacteria; examination of a second drop showed none. The mystery was soon explained; he had cleansed his pipette before taking the first drop with distilled water, a drop of which had remained in the tube, and which contained, as examination of the water in the bottle revealed, numerous bacteria. In these days pipettes are cleansed, not with distilled water, but by a Bunsen flame; knives, needles, test-tubes, flasks, etc., are considered sterilized after heating for five minutes to 150° C.; and fingers are allowed under no circumstances to touch anything which could possibly come into subsequent contact with the culture.

A consideration of the difficulties thus briefly sketched in the way of even the accurate recognition of bacteria, discloses the value to be attached to many publications concerning these organisms—which exhibit but too often the author's neglect to comply with, sometimes even his ignorance of, the elementary requirements of principles and practice. As illustrations I shall select from the mass of literature of this description a few which, from the eminence of their respective writers in other departments of medicine, have attracted considerable attention without as well as within our professional ranks. Some four years ago a most genial and accomplished gentleman, an eminent practitioner of New England, made a tour of our large cities with the benevolent object of instructing his professional brethren as to the etiology of tuberculosis and of syphilis. He asserted the discovery in the blood of such patients of "germs" not found in other blood; he exhibited a series of transparencies in which granules—the germs—were shown in the blood; he showed a loaf of bread which had been fermented by organisms from the defection of tuberculous and syphilitic patients. The good work was not limited to the medical profession; a noted Boston clergyman delivered a Monday lecture upon this subject, in which the doctor's blood-granules, projected upon a screen, posed before the conscience-smitten audience as the avengers through whose dread agency the way of the amorous transgressor sometimes becomes hard. Only two links were lacking in the chain of evidence; first, there was not the slightest proof, nor attempt at proof, that the blood-granules were germs; second, it was unfortunately demonstrated that identical granules were usually found in healthy individuals.

A few weeks ago the startling discovery was announced that the famous bacillus tuberculosis was a fat crystal. A distinguished pathologist, failing to detect the bacilli in tuberculous tissues, treated his sections with a thirty per cent. solution of caustic potash, whereupon crystals of fat of course appeared. These crystals are al-

leged to be identical with the bacilli tuberculosis; therefore these organisms exist only in the imagination of benighted individuals who blindly follow Koch.

Now what proof is adduced that the crystals and the alleged bacilli are identical? Merely that they have the same size and shape. When we remember that the discoverer of the crystals had never seen the bacteria in question, we can admit that the former have the same size and shape as the bacilli of Dr. Schmidt's imagination, but not necessarily as the actual organisms. A comparison of the two demonstrates, as Dr. Schmidt has recently learned by personal observation, that they are widely different, even in appearance. But, assuming that in size and contour Schmidt's crystal and Koch's bacillus were similar, would that justify the assertion of their identity? Evidently not to an individual whose conception of a bacterium comprises something more than size and shape. The crystal cannot be made to absorb and retain aniline dyes, as Dr. Schmidt expressly states; the bacillus, like other bacteria, is readily stained by any one of several aniline colors. The crystal, we may assume, does not grow nor reproduce; the bacillus elongates, divides, and produces in its substance two or more globular bodies, which in turn grow into rods. Dr. Schmidt fails to appreciate these vital differences; ignores the absorbent and reproductive powers of the true bacilli, attested by a score of competent observers. For him size and shape are enough, and upon this fancied resemblance of his crystals, in outline, to bodies that he has never seen, he assumes their identity. I shall consider Schmidt's paper in the discussion of tuberculosis, and make this allusion here because it illustrates admirably the fact that even in these latter days publications about bacteria, by men of experience in other departments of medicine, even in pathology, evince a failure to appreciate the first principles of mycological investigation.

To ascertain the relation to a disease of bodies whose bacterial nature is thus recognized, and which are found in the blood or tissues of a diseased animal, it is evident that the first step must consist in the perfect isolation of the bacteria from the enclosing tissue; since otherwise the possible effect of inoculation may not be ascribed to the bacteria rather than to the accompanying unorganized substances.

The isolation of bacteria from the blood and tissues of an animal has been attempted chiefly in two ways: by simple filtration through paper, clay, or other porous substance, and by artificial cultivation. Filtration is evidently a very unsatisfactory attempt at isolation; the separation of the smaller bacteria, especially micrococci, is practically impossible; and since other ingredients of blood or tissue are or may be retained on and in the filter, the proof of isolation is not convincing. In artificial cultivation advantage is taken of the fact that the bacteria reproduce indefinitely, while the animal tissues of course do not. A drop of blood or pus, or a particle of tissue containing the bacteria, is placed in an appropriate nutrient medium in a flask, tube, or other receptacle. In a few hours or days the organisms have become diffused, by virtue of their rapid multiplication, throughout the entire liquid. A drop, or fraction of a drop, of this fluid containing bacteria, is then transferred to a second vessel similarly prepared; after the growth of the organisms in this, a minute quantity is transferred to a third flask, and so on indefinitely at the will of the operator. In this way the bacteria can be practically isolated from the animal tissues introduced with them into the first culture vessel; and the effect of inoculation from the tenth, twentieth, or thirtieth successive culture cannot be reasonably ascribed to the unorganized constituents therein contained. But it is evident that in order to attribute the effect of such inoculation to that particular bacterial species contained in the diseased animal, one must be absolutely certain that no other variety has obtained a foothold in the cultures—that the original bacteria are

isolated not only from the animal tissues—a comparatively simple matter—but also from all the other varieties of bacteria—which seem omnipresent. And just here is the difficulty which has been until recently almost insuperable; here is the possible source of error which weakens materially some brilliant deductions from experimental work; and this possibility of error is the basis of the general criticism which Koch urges against Pasteur's work—a criticism which, as is evident from a comparison of methods, is not without foundation. Although numerous modifications of culture methods have been employed, all may be grouped in three general classes. The first, the earliest, and by far the worst, is cultivation in flasks, tubes, or other vessels containing the nutrient liquid, usually in large quantities—one or more ounces. This method, thanks to its adoption and retention by Pasteur, as well as to the facility of its manipulation, has secured an unfortunately extensive and persistent employment. The defects become apparent when we consider the vital properties of bacteria. Different species require different pabulum and various temperatures for their successful cultivation. The bacillus subtilis (Cohn), for example, grows luxuriantly in a simple infusion of hay, which is ordinarily slightly acid in reaction; the bacillus anthracis, which is morphologically similar, indeed almost identical with the former, grows very slowly or not at all in the same infusion; the addition of a little magnesia or other base, sufficient to render the liquid somewhat alkaline, reverses the relative reproductive activity of the two. The hay bacillus (*b. subtilis*), again, can reproduce at a temperature incompatible with the reproduction of the *b. anthracis*. If, then, the two be sown in the same sterilized hay infusion, the crop will be determined largely by the reaction and by the temperature of the liquid. Another feature to be remembered is the variable rapidity with which different species multiply, even under the most favorable surroundings; for as Nägeli has shown, if two bacterial varieties, A and B, be present in a liquid adapted to each, A dividing its cell into two in twenty-five minutes, B in forty minutes, the latter, even if present at first in 1,800,000 times the number of the former, will in eighty hours have been stifled by A. In a mixed cultivation—in other words—the quickest to propagate will, *ceteris paribus*, in a few hours or days remain alone—a principle with whose applicability to higher organisms we are of course familiar. It is evident, then, that the best method of isolation is that which affords (first) the greatest security against the intrusion of other organisms than that under cultivation, and since such intrusion cannot by any method at present employed be with certainty prevented (second), the greatest probability of the detection of such invasion by other bacteria. The isolation cultures in flasks suffer the same dangers of adulteration as other methods, aggravated somewhat by the increased difficulty of sterilizing large quantities of the nutrient material. These dangers recur with the institution of every new culture; for in order to secure isolation of the organisms from the blood or tissue which accompanied them into the first flask, many transplantations must be made. Successful induction of infection by inoculation from the first culture is, of course, met by the objection that the liquid contains solid or fluid unorganized ingredients from the animal diffused through it, and that the effect cannot be attributed to the contained bacteria alone.

With every transfer to fresh culture fluid the possibilities of adulteration by intrusion of other organisms contained in the liquid, the flask, the air, etc., are encountered; moreover, the last culture, however long the series may be, is theoretically, at least, a dilution of the animal juices present in the first flask, although by many successive generations the dilution becomes homeopathic and may be practically disregarded. That this danger of the intrusion by other bacteria during transfer, however carefully done, is not trivial, is known to every experienced observer. Mr. Cheyne ("Antiseptic Surgery,"

page 261) says: "In the room in which I work I have never been able, without the aid of the spray, to transfer micrococci from one flask to another. For in the latter flask bacteria" (in the generic sense) "almost invariably developed."

The chief objection to flask- or tube-cultivations, however, one which renders them utterly unsatisfactory as attempts at isolation, is the impossibility of detecting with certainty the presence of foreign organisms. Some varieties, it is true, indicate their presence macroscopically, but the absence of them does not prove the absence of others. One is compelled to remove the cotton, withdraw a drop of the liquid, and submit it to microscopic examination—a proceeding perilous to the purity of the culture. But even in this way no certainty can be assured, for the one drop may be free from intruding organisms, which may nevertheless be present in the flask. More than that; since many varieties, at least many bacteria growing under different circumstances, are morphologically indistinguishable, one is not always certain that the organisms found are really the offspring of those planted rather than morphologically identical intruders. Suppose, for example, we are attempting to isolate the micrococci found in the blood of a pyæmic patient; on examining a drop from our tenth generation, our tenth successive flask, we find only micrococci identical in appearance with those planted. Are we warranted in asserting that these are the descendants of the organisms seen in the blood? To answer the question affirmatively we must assume first that the micrococci contained in the blood were the only ones which gained access to the first flask; then that our ten flasks, ten liquids, ten stoppers were rendered and remained sterile; that our pipettes, forceps, etc., have been always free from organisms, and that during the nine transfers, and perhaps numerous test examinations, no micrococci have gained access to our cultures from the air—an assumption not warranted by experience. By such assumptions Bastian demonstrated spontaneous generation.

A source of possible error in these methods, not always recognized, is the necessary assumption that apparent community of form among bacteria proves identity of function. The fallacy of such assumption is *à priori* evident, and has been repeatedly demonstrated. A Cyclops whose exaggerated retina might fail to distinguish objects less than three feet in diameter, could perceive no morphological characteristics wherein a wolf differs from a sheep, and could have no conception of the perversity which distinguishes a mosquito or a wasp from the house-fly. In 1875 even Cohn pronounced the harmless bacillus subtilis of hay infusion morphologically identical with the bacillus anthracis; to-day we can, thanks to improvements in technique, distinguish the latter not only from the hay bacillus, but also from two other important varieties which are morphologically extremely similar, though physiologically quite distinct. Further research may possibly reveal differences of form even among the minute bacteria. But granting that two micrococcus varieties are actually, as well as apparently, identical in form, that alone proves identity of function as conclusively as the morphological identity of two sugar-coated pills, containing arsenic and bread respectively, establishes the unity of their effects.

I have considered this subject at such length because it will be necessary, in the course of these lectures, to criticize certain experiments, and reject as not proven certain conclusions, because attained by this method of cultivation in liquids. The solution of many problems would be, in my judgment, materially hastened, and much conflict and confusion avoided by the substitution for this still popular method of one demonstrably far more accurate, to be presently described. Flask- and tube-cultures are certainly convenient for cultivation *en masse*, but evidently imperfect for investigations as to the rôle of bacteria in disease.

The fact that bacteria growing under different condi-

tions, and apparently functionally different, are morphologically identical and all so widely distributed and ubiquitous, renders it evident that one condition must be fulfilled in order to demonstrate conclusively and finally that the organisms present in a culture at a given moment are the progeny of those previously planted by the experimenter; the former must be observed *to proceed by continuity of structure*, from the original bacteria. In this way, and thus only, can all doubt and objection be silenced; all possibility of misinterpretation be eliminated. The first requisite for the execution of this method is evidently continuous observation of the growing bacteria through the microscope; a method long used. A drop of nutrient liquid is placed on a cover-glass, the bacteria sown therein, and the cover inverted over a hollow slide or a cell of glass cemented to the slide; the edge of the cover is then or previously smeared with oil, for the double purpose of limiting evaporation from the droplet and of preventing the intrusion of foreign substances or organisms.

If foreign organisms capable of growing in the liquid obtain, by any error of manipulation or other means, access to the droplet, they may become in a few hours diffused throughout its extent; if perceptibly different in size or shape from the variety sown, the intrusion may be detected and the culture abandoned; if morphologically indistinguishable, the intrusion cannot be detected, the culture is considered pure, and lamentable errors of interpretation may result. Even in Koch's skilful hands nearly one-half such cultures were found to contain foreign organisms.

Such, then, were the methods of attempted isolation in general use until three years ago, and unfortunately still extensively employed; methods which, even in skilful hands gave conflicting results, and in inexperienced hands have demonstrated incredible things. By these methods spontaneous generation is easily proven; the metamorphosis of a pathogenic into an innocent bacterium, and conversely, is established with great facility; in fact almost any plausible hypothesis can, with a reasonable amount of ingenuity and inexperience, be clearly demonstrated. It is difficult to conceive, indeed, a shorter road to scientific notoriety than by the cultivation of bacteria in flasks—an opportunity already amply improved. One need only extend his series of successive cultures long enough, make transfers and pipette examinations often enough, permit the temperature of his oven to vary a little, perhaps spice his work with a touch of the fashionable evolution hypothesis by varying the composition of his culture-fluids so as to invite the growth of various organisms, and, presto! there appears a conclusion whose adoption would revolutionize mycology, medicine, and perhaps modern society. A bacillus may be made to grow out of a bacterium, this out of a micrococcus, or any of them out of nothing. A bacillus anthracis can, in the course of fifteen hundred transfers, be robbed of its terrors—the leopard can change its spots, the lion can become a lamb.

Three years ago there was introduced—thanks to the ingenuity of Koch—a method which avoids, theoretically and practically, the difficulties inseparable from previous attempts at isolation of a given bacterial species found in an animal, both from other varieties and from the accompanying animal juices. The essential feature of this method consists simply in the substitution of a solid—transparent when possible—for the liquid material adapted to the nutrition of the organism.

The general plan is as follows: a solution of gelatine, beef-extract, pepton; or blood-serum, the relative proportions of the various ingredients varying with the species to be cultivated is sterilized by repeated heating and then spread as a thin layer upon a disinfected slide and allowed to dry or coagulated by heat. A previously heated needle or scalpel is then dipped into the material containing the bacteria—septic mouse-blood, for example—and drawn lightly over the surface of the culture substance on the

slide, or a series of punctures are made with the point. Thus a number of shallow furrows may be made, in and on the edges of which the bacteria are deposited. The slides so prepared are then transferred to the incubator or placed under a bell jar; or, if they are to be long preserved, in a thoroughly disinfected vessel

Fig. 2.—Anthrax bacilli growing from rabbit's liver, on blood serum. $\times 40$. (This and succeeding cuts are copied from original photomicrographs.)

closed with cotton. A disadvantage of this method, like that with liquid media, is the uncertainty of sterilizing the nourishing medium; further, the occasional settlement and growth of foreign organisms in the vicinity of those planted. Yet these accidents are in this method, in distinction from others, detected with ease and certainty. For there is no diffusion through this solid medium of growing bacteria; each organism, whether intentionally planted or not, remains in one spot, any admixture must occur by continuity of growth.

Fig. 3.—Anthrax bacilli, pure (isolation) culture on blood serum. $\times 140$.

By this method, then, there is ocular demonstration that the organisms of the successive cultures proceed as continuities of structure from those of the first; we may see the bacteria in the leucocytes of septic blood freshly deposited on the first slide, watch them multiply until they break out of the containing cell and extend over the ge-

latine, transfer these to a second slide, observe their continued multiplication, and so on indefinitely. By this method, and by no other at present employed, we have ocular demonstration that the organisms injected into an animal from the tenth, fiftieth, hundredth culture are structural continuities of the organisms present in the first animal; by this method we know that the tenth culture, for example, contains absolutely nothing of the original tissue except that incorporated into the living organisms; by this, and by no other method with which I am acquainted, it may be unhesitatingly affirmed that the effect induced in a healthy animal by inoculation with the tenth, twentieth, or fiftieth culture must be ascribed not only to bacteria, but to the direct descendants of those bacteria contained in the animal from which the first cultures were made. And permit me to add that after such demonstration has been furnished in scores of repetitions with identical results, by independent competent observers, by every one indeed, who has attempted it, it is unwise and unreasonable, to put it mildly, for any of us to deny, oppose, ignore, scoff at, or equivocate about a fact established far more firmly than are the majority of accepted facts, so called, in the science and art of medicine.

A consideration of importance in estimating the value of observations upon bacteria, is the microscopical technique employed by the observer. That good objectives should be used is well understood; but it is now essential also, in delicate investigations, to employ a condenser made after the pattern of Abbé's illuminator. The feature which makes this apparatus invaluable in the detection of bacteria is the possibility of obliterating, through the large aperture of the lenses, the picture of the object due to refraction, thus practically eliminating

Fig. 4.—Anthrax bacilli—showing spore formation. $\times 300$.

from the field of vision everything which is not colored. Bacteria not only absorb coloring matter—aniline dyes, for instance—but retain these pigments in the presence of reagents which decolorize the animal tissues, generally speaking. To detect a minute organism, the bacillus tuberculosis, for example, amid the cells, fibres, and granules of lung-tissue is, with ordinary illumination, extremely difficult or impossible; but after decolorizing the tissue and then, by means of the illuminator, obliterating refraction outlines, the bacilli appear almost alone, by virtue of their retained color, in a luminous field—distinct and easily recognizable. When, therefore, an observer asserts the absence of all bacteria from a tissue—tuberculous or leprous, for example—usually supposed to contain them, it is in order to inquire first whether he knows

how to use the aniline dyes, and second, whether he has the optical means, an Abbe's or similar illuminator, necessary to enable him to utilize these staining methods in the detection of bacteria; if he lack either he is but ill-equipped for public entrance into the arena of original investigations on this subject; for both are essential to the development of the histologist into the medical mycologist.

Fig. 5.—Anthrax culture invaded by other bacteria. $\times 300$.

I have thus endeavored, Mr. President, to sketch the principles involved in the study of bacteria, in order that we may on subsequent occasions form a somewhat accurate and intelligent estimate of the evidence already adduced as to the relations of these minute beings to various morbid conditions of the human subject. If the effort to convey the facts has been successful, you will agree that an original contribution to this evidence demands serious consideration only when it evinces, on the part of its author, not simply skill and experience as a microscopist and histologist, but also a practical acquaintance with and employment of the special methods and manipulations necessary for the recognition and cultivation of bacteria. Medical mycology has become a special department of investigation, comprising most delicate and easily vitiated technical methods, to be acquired by special study and experience; the time has passed when the ability to focus a quarter-inch objective entitled a man to an opinion upon the subject. Medical mycology may not be compared in age or attainments with chemistry; yet the necessary technique is as delicate in the one as in the other; and there exists therefore the same necessity for the recognition of individual knowledge, and by consequence of general ignorance of the one subject as of the other. I am led to indulge in these rather commonplace remarks by the observation that there is a more or less prevalent lack of appreciation of the evident facts in the case; witness the recent discovery of the pseudo-bacillus tuberculosis and the comments thereupon in current literature and society meetings. Not a few medical journals announced the complete annihilation of the bacillus tuberculosis in particular and bacteria in general, a dictum pronounced by a witty rural editor, equally familiar with mycology and Latin syntax, in the words—"Sic transit bacteria." Even a leading New York journal remarked that "the case against the bacilli is very strong." If it should be announced by Dr. A. that pyæmia is not characterized by an excess of carbolic acid in the urine, as asserted by Brieger, we practising physicians would not undertake to decide; we know too much about chemistry. There are at present perhaps a score of men who have given abundant evidence of competence in bacterial investigations;

to them and to such as they, not to dermatologists, surgeons, or pathologists, we must look for facts upon this subject, and for experimental criticisms of one another's assertions.

Before discussing the relations of bacteria to the body in disease, it is well to consider their relations to the animal in health and after death. It is a much disputed question whether any varieties of bacteria may exist in the blood or tissues of a healthy animal. In former years the affirmative was maintained by many, notably Billroth; with improvement of methods and differentiation between organized and unorganized particles the number of such affirmations decreased; and the three most noted observers of the present day—Koch, Pasteur, and Ehrlich—affirm that they have never detected bacteria in a healthy animal. Numerous attempts have been made to decide the question experimentally—by the history of healthy tissues, transferred under precautions against contamination, from the living or dying body to conditions of perfect isolation from bacteria. Such experiments demonstrate that some healthy tissues, at least, contain no organisms capable of inducing putrefaction; as the majority of bacteria are, however, incapable of effecting this process, the failure to putrefy does not necessarily prove the absence of all bacteria. Observation and experiment on the living body would also prove the absence of bacteria from healthy animals. The familiar fact that a dead human fetus may remain in the mother's body for months or years without putrefaction, as in extra-uterine pregnancy, supports the same conclusion. Indeed, it has been repeatedly demonstrated that certain bacterial species, even when injected in considerable numbers directly into the blood or tissues of the living animal, cannot be found after the lapse of some hours; they appear to suffer the same fate as unorganized particles. Hiller even injected into his own skin some bacteria obtained from putrid flesh, and observed only a slight, transient, local oedema.

This failure of putrefactive and other bacteria to reproduce in healthy tissue seems to indicate their inability to maintain the struggle for existence against the animal cells indigenous to the soil. For seventy years a man may eat, drink, and breathe the ordinary bacteria, and carry a vast and varied assortment of them in his alimentary canal, without suffering putrefaction; yet so soon as his component cells are destroyed, generally, as in the death of the animal, or locally, as in the gangrene of a toe, the tissues swarm with these minute organisms. While some bacteria seem capable of development in tissues only after the death of their competitors, the animal cells, others exhibit this power in the presence of these cells when the tide is turned against the latter by the impairment of their nutrition, or by the presence in the blood of material favoring the invaders. The exudate on the cardiac valves frequently contains, not only in ulcerous, but also in simple "rheumatic" endocarditis, colonies of growing micrococci, a fact first observed by Klebs and confirmed by Eberth, Ehrlich, and Osler. In some cases it is demonstrable that the appearance of the bacteria upon these vegetations was subsequent to the inflammatory process. Abnormal blood composition seems to favor the development of some bacteria which may gain access to the tissues. The presence of glucose and increased metamorphosis of albuminous blood-constituents in diabetes are usually considered responsible for the proneness of diabetics to abscesses, carbuncles, cataracts, gangrene of wounds, sloughing of stumps even under most careful antiseptic dressings. These spontaneous abscesses and carbuncles contain, when freshly opened, micrococci in a high state of activity, as shown by Kraske, Eberth, and Pasteur. A clinical observation in the history of diabetics, their susceptibility to consumption, acquires peculiar significance in this connection, since the presence of the bacillus tuberculosis is now certainly a recognized anatomical characteristic, whatever may be said of its etiological relation. Cheyne

refers to a weak, cachectic patient who had an abscess wherever he received a bruise, and whose abscesses always contain micrococci. Another question, formerly much disputed, is the possibility of invasion of animal tissues by bacteria without previous solution of continuity. The only possibility for discussion now remaining is as to what shall be considered a solution of continuity; for it is definitely demonstrated that these organisms gain access to the body without the existence of any wound or abrasion discoverable upon the closest scrutiny. Trichinae force their way from the intestine into the muscles; particles of coal are conveyed, probably through the agency of white corpuscles, into the parenchyma of the lungs, bronchial glands, and even the liver; it would seem *a priori* certain that many bacteria, much smaller than these particles, could also be received into the tissues. Ogston, using the most approved technique, found micrococci in every one of seventy previously unopened acute abscesses. Cheyne reports a similar experience. Micrococci have been repeatedly observed in the blood in spontaneous pyæmia, osteomyelitis, etc., and Obermeier's spirilla in recurrent fever patients, in cases where no lesion of the integuments was discoverable. But the question seems to have been finally decided by experimental demonstration. Buchner has induced anthrax in animals by the inhalation of powdered material containing the spores of the bacilli. When we remember the endothelial nature of the cells lining the pulmonary alveoli, we readily appreciate the facility with which particles, large or small, organized or unorganized, gain access to the circulation through the lungs.

Bacteria, then, which, by virtue of their ubiquity, are in constant and frequently recurring contact with the animal body, are, like other minute bodies, organized and unorganized, frequently introduced into the body through solutions of continuity of the integuments, or through intact skin and mucous membranes, particularly by way of the lungs.

The burning question in pathology to-day is, In what degree are the various species of bacteria, present in human tissues during certain morbid conditions, to be regarded as the cause of the morbid processes with which they are respectively associated? Having already reviewed the conditions of eligibility for witnesses and of authenticity for evidence, we are prepared to consider in detail the present state of the question as to the individual diseases.

Before admitting the causal relation of a bacterium to the disease, we must be convinced not only that all observed phenomena can be easily reconciled with such assumption, but also that they can be as plausibly explained by no other assumption. The evidence of such casual relation must establish, therefore, the competence of the observer and the accuracy of the observation; the presence of a constant bacterial form in every case of the disease, and in numbers sufficient to explain the morbid phenomena; the demonstrable isolation of the bacteria by successive cultures; the induction of the disease in numerous healthy animals by inoculation with the isolated organisms; the reproduction of the same bacterial form in the inoculated animal. Gauged by this standard, the evidence already adduced warrants the following unscientific but convenient classification:

First.—Disease, the demonstration of whose bacterial origin has been completed, through inoculation with isolated bacteria, by several competent observers—anthrax.

Second.—Disease whose bacterial origin has been affirmed, after inoculation with isolated bacteria, by one competent observer—tuberculosis.

Third.—Diseases which are uniformly characterized, *intra vitam*, by the presence of bacteria in the tissues; but which have not as yet been induced by inoculation with the isolated bacteria—recurrent fever, pyæmia, diphtheria, erysipelas, leprosy, rhinoscleroma, gonorrhœa (urethræ et conjunctivæ), and some forms of septicæmia. Puerperal fever, osteomyelitis, and ulcerous

endocarditis are considered to belong etiologically with pyæmia, septicæmia, erysipelas, and diphtheria.

Fourth.—Diseases after death from which (in some cases also during life) bacteria have been observed in the tissues: variola, scarlatina, typhoid fever, croupous pneumonia.

Fifth.—Diseases in which the presence of bacteria, ante or post mortem, has been asserted: syphilis, intermittent fever, yellow fever, typhus, measles, lupus, rabies, tetanus, *et al.*

The investigation of the diseases included in the fourth and fifth classes is as yet quite imperfect and inaccurate, partly at least because they are with few exceptions peculiar to man.

The evidence as to the relations of bacteria to disease rests largely upon experimental observations upon the lower animals. The impossibility of thorough examination of human tissues, not only during life, but also for hours or days post-mortem, restricts materially the field of clinical observation on this subject: for a few days, even hours, suffice to people a dead body with bacteria. We may simply ignore such contributions as that of Zander (*Virch. Arch.*, Bd. LIX.), in which he announced the probable discovery of the bacterial origin of acute yellow atrophy of the liver. In one fatal case of the disease he found bacteria in the liver, the section having been made fifty-four hours after death. He anticipates the possible objection that the bacterial development was perhaps post-mortem, and refutes it with the convincing statement that "the body did not, so to speak, exhibit any marked symptoms of putrefaction." Indeed, while defective methods may be chiefly employed by the practically inexperienced, most egregious misinterpretation is unfortunately not monopolized by them. Several pioneers in this subject, notably Pasteur and Klebs, have, by the publication of hasty and, as subsequently appeared, erroneous conclusions, forfeited much of the prestige acquired by their earlier classical works on fermentation and gunshot wounds respectively. These two observers have ignored successive improvements in technique; have apparently assumed that all infectious diseases are of bacterial origin; that therefore the discovery of a bacterium in a diseased animal is ample proof of its pathogenetic influence. Years ago, Klebs announced the discovery of the bacterium of tuberculosis, and even declared that the disease could be cured by an agent, benzoate of sodium, which destroys the parasite. With equal facility he discovered the bacterial origin of syphilis, typhoid fever, etc.

Pasteur seems to have a fondness for micrococci, especially in the figure of 8 form, to which he ascribed puerperal fever, rabies, his "nouvelle maladie," as well as chicken cholera, and typhoid fever. His famous publications about the inoculation of chickens with anthrax, and about the rôle of earthworms in transporting anthrax spores, further illustrate the inability of his judgment to cope with his imagination.

EDUCATION AND CRIME IN FRANCE.—In a report on the connection between education and crime the records of the courts of France show the following result, which is directly opposite to the records for the United States: 1. That 25,000 persons of the class wholly illiterate furnish five criminals. 2. That 25,000 of the class able to read and write furnish six criminals. 3. That 25,000 of the class of superior instruction furnish more than fifteen criminals. 4. That the degree of perversity in crime is in direct ratio with the amount of instruction received. 5. That in the departments in which instruction is most disseminated crime is greatly more prevalent—in other words, that morality is in inverse ratio with instruction. 6. That relapse into crime is much greater among the instructed than the non-instructed portion of the community.

SUCCESSFUL CASE OF LAPAROTOMY FOR ACUTE INTESTINAL OBSTRUCTION, DUE TO STRANGULATION; WITH REMARKS.

By PROFESSOR LÉON LE FORT,

SURGEON TO HOTEL DIEU; PROFESSOR OF OPERATIVE MEDICINE TO THE FACULTY; MEMBER OF THE ACADEMY OF MEDICINE, PARIS, FRANCE.

INTESTINAL obstruction by volvulus, by invagination, by constricting bands, imposes on the surgeon a problem whose solution is often difficult. If he decides on intervention by a capital operation, he must choose between enterotomy and laparotomy. Enterotomy is limited to an incision of trifling extent through the abdominal walls into the peritoneal cavity, where a loop of intestine is sought above the obstruction, of whose site and whose nature the operator is generally ignorant. A small opening is made in the intestine, and exit given to gas and fecal matters.

In laparotomy the abdomen is freely opened by a large incision, which enables the surgeon to hunt for the obstacle without any hindrance, and, having found it, to overcome it, whether it be an invaginated intestine, the twists or knots of a volvulus, or strangulating bands.

Laparotomy, practised in France by Dupuytren, by Malgaigne, and in 1859 by Depaul, performed a little oftener in England since 1847, did not win favor with French surgeons, and under the influence, more especially of Nélaton and his followers, enterotomy, in spite of the want of success which almost always attended it, was for a long time the only operation employed. However, the past twelve years, since ovariectomy has been in fashion and has demonstrated that the danger of free incisions into the abdomen has been greatly exaggerated, there has been a reaction in France in favor of laparotomy, which to-day tends to take the place of enterotomy.

I do not intend to discuss the relative value of the two operations; I limit myself to mentioning the principal reason which leads me to prefer laparotomy to enterotomy. In 1865, that is seventeen years ago, I pointed out the danger of purgatives in hernial strangulation, advising the substitution of opium. I sought to show what at this epoch had not been clearly stated, that the dangers from strangulation do not depend on retention of fecal matters in the intestinal tube, but on the reaction occasioned throughout the entire ganglionic nervous system by irritation of the splanchnic nerves included in the portion of intestine strangulated. In fact, in peritonitis, in strangulated omental hernia, in the orchitis of a testicle retained in the spermatic canal, we have the principal phenomena of strangulation: vomiting, absence of stools, smallness of the pulse, coldness, alteration of the features, and at the same time there is no material obstacle to the evacuation of the intestines. On the other hand, after operating for strangulated femoral hernia, I have known the bowels to be confined for five, six, and even nine days after the operation, by reason of the administration of opium; and yet all the dangerous symptoms began to disappear as soon as the strangulation was remedied. In short, who, conversant with the facts of speedy death from traumatic peritonitis, or peritonitis from perforation, can suppose that a few drachms of effused liquid of an irritating kind in the peritoneum may so quickly give rise to fatal symptoms; or who, believing this, can explain by what mechanism death takes place?

The theory, then, that I have maintained and taught for many years, is that the unfavorable symptoms in all these cases of peritonitis and strangulated hernia, whether of the intestines or omentum, are due to irritation of the splanchnic nerves (of the intestine or omentum) by the band constricting the gut, and in some measure by the over-distention of the bowel; an irritation, moreover,

which is reflected on the great abdominal sympathetic, and through it on the heart.

Without doubt the excessive distention of the intestine by gas and fecal matters accumulated above the point of obstruction adds another source of mischief, but the primary irritation, the constricting band, is infinitely more grave in its consequences, and will almost inevitably result in death to the patient, even when by enterotomy the intestine above the obstruction has been opened, and the contents of the bowels evacuated by a false anus.

It is because laparotomy gives us hope of being able to arrive at the original cause of the evil, and thus remove it, that I prefer laparotomy to enterotomy.

I am obliged to admit, however, that errors in diagnosis are not at all rare in these circumstances. I shall never forget my first operation for laparotomy, in 1870, when, with the aid and concurrence of my friend and colleague, M. J. Bucquoi, of the Hôpital Cochin, I operated on a patient in his service. The opening of the abdomen disclosed not a strangulation by organized lymph, or by volvulus, as we supposed, but a cancer of the sigmoid flexure of the colon, causing complete obstruction of the bowel.

It is easy to understand why, in these conditions of uncertainty, the surgeon should hesitate to freely open the abdomen, and prefer an operation less terrifying to the patient and his family. Enterotomy having (wrongly) the reputation of being little dangerous in itself, it seems to the surgeon less painful, in the event of want of success, to discover at the autopsy an error in diagnosis than to discover this error at the moment when, by a large incision, he has exposed to view the viscera of the abdominal cavity of his patient.

However, facts only can carry conviction, and for several years laparotomy, which counts many cases of success, mingled, it is true, with failures, has been growing in favor with the profession.

In the following observation, where the operation of laparotomy was performed under very disadvantageous circumstances, I do not believe that enterotomy would have saved the life of the patient. Merely giving issue to the gases and liquids of the intestine would have been a sorry relief, when a constricting band was suffered to remain, provoking irritation and inflammation by compression of the intestine, engendering, in fact, a peritonitis, which would in all probability have been fatal had not laparotomy come to the rescue of the patient. I have copied the report from the memoir presented to the Academy, believing that it would interest the readers of the *NEW YORK MEDICAL RECORD*.

Observation.—The first day of last June (1882) I was called to Colombes by Dr. Tachard, to see a young man of eighteen years of age, suffering since the 25th of May, that is to say one week, from internal strangulation. My confrère gave me the following history of the case:

During the evening of the 25th of May, the patient experienced some pain in the abdomen, which about midnight took on the character of violent colic. Dr. Tachard called in the night-time, ordered a laudanum injection, innunctions of belladonna to the abdomen, and hot poultices. The next day the pains were on the increase, the belly was sensitive to the least pressure, somewhat distended, and since the morning of the day before there had been no passage from the bowels. A dose of castor-oil was given, which was immediately vomited; then a copious enema was administered, which came back without bringing away any fecal matters. As the patient had a small inguinal hernia on the left side, attention was directed to that, but as the hernia was found to descend and to return with all ease, it was evident that the cause of the trouble was elsewhere.

The complete absence of evacuations, the persistence of the vomiting which soon became incessant, the absence of fever, the alteration of the features, the smallness of the pulse, seemed to justify the diagnosis of internal strangulation. This diagnosis was rendered still

more probable by the fact that in 1879 the patient had had an attack of subacute peritonitis, which would have been likely to leave troublesome sequels in the form of bands of organized lymph and adhesions.

The condition of the patient becoming alarmingly worse, the family asked for a consultation, and the 29th of May, that is to say the fourth day, a confrère from Paris, who in 1879 had attended the patient, was summoned. He counselled purgatives, which had no favorable result. It was then that Dr. Tachard, seeing the patient growing worse all the time, declared to the family that, in his opinion, nothing but a surgical operation could save the patient. The family inflexibly opposed any operation, and it was not till three days after (June 1st), the seventh day of the strangulation, when death seemed imminent, that it was decided to summon me in consultation.

When I saw this young man in the evening of the day above mentioned, I found myself in the presence of an apparently moribund patient. His countenance bore a pinched expression, his body was covered with a cold sweat, his extremities were cyanosed, and icy cold. The pulse was small and rapid, and the least movement brought on fecal vomiting. The abdomen was tympanitic; the markings of the intestinal convolutions could be seen on the abdominal walls.

There was, however, no exaggerated sensitiveness to pressure, no dulness or obscurity of sound in the lateral and inferior portions, nothing which could lead me seriously to suspect the existence of peritonitis. I represented to the family that the chance was a forlorn one, but without surgical intervention the case was hopeless. I was willing to attempt what could be done by gastrotomy, though the patient might die in the operation. The family having left all responsibility in the matter to me, I proceeded to operate, with the assistance of Drs. Tachard and Ducor.

The patient having been partially anæsthetized with chloroform (which was charily administered on account of the prostration), I made an incision, fifteen centimetres in length, in the linea alba, from the umbilicus to the pubes, and with the usual precautions. As soon as the abdomen was opened, coils of the distended intestines protruded. We took pains, with our outspread hands, to keep back all but a few coils, which I returned as soon as I had examined them, drawing out carefully, little by little, other portions of the intestinal mass, and scrutinizing them closely before putting them back; we thus drew out through the opening in the abdominal wall, in successive portions, the larger part of the small intestines before the seat of the obstruction presented itself to our view. One of the coils resisted my attempt to bring it out by the incision; I felt that I was near the obstruction. Then, following with my hand into the abdominal cavity the resisting loop of intestine, which was considerably distended, I found, near the right iliac fossa, a little tumor, formed by hardening and agglomeration of the intestine, and I discovered that the intestinal loop which I was following with my finger, engaged itself in a tight circular aperture, which seemed as if formed by a firm membranous cord. Hooking the extremity of my index finger into this constricting ring, I drew carefully to the surface, on a level with the abdominal opening, a coil of congested coarcted intestine, and we had under our eyes a band, a sort of fibrous ring, very resisting and very thick, formed by organized adhesions, and which encircled the small intestine five centimetres (or thereabouts) from its termination in the cæcum. I cut the band, which was about five millimetres in width, with a few clips of my scissors, and thus released the intestine.

The small intestine was congested throughout almost its entire extent, but there was no fluid in the peritoneal cavity; peritonitis had not as yet set in, and at the site of the stricture, despite the long duration of the malady, the vitality of the intestine did not seem to be compromised, the stenosis not having been absolute.

The intestine was returned, and the wound in the abdomen closed by seven deep silver-wire sutures, passed separately through and fastened to a bougie. I then put in a dozen superficial sutures in the ordinary manner.

In the night-time the patient had a large stool, very fetid, and for several days following copious alvine evacuations. The patient, though very weak, was restless and intractable, not comprehending the necessity of absolute repose. The seventh day after the operation he rose suddenly in bed, in a state of agitation, and the superficial sutures gave way, letting the wound gape open. Fortunately, union of the deeper parts was effected, so that the abdomen was not opened. Being summoned to the patient, I applied several new sutures, using the quilled suture, and three days after, Dr. Tachard applied an abdominal belt, with pads nicely adjusted to the sides of the wound, to secure exact approximation. Cicatrization was effected in a few days.

Convalescence went on favorably, and by July 1st the patient was able to go abroad.

It is now seven months since the operation, and a curious and most gratifying change has been effected in the condition of this young gentleman, who previously was thin and in delicate health. The difficulties of digestion, the obscure abdominal pains from which he had suffered from the time of his attack of peritonitis in 1879 down to the date of the operation have all disappeared, and his health is now excellent. He has become stout and fleshy, so as hardly to be recognized by those who knew him a year or so ago. There is now no trace of the old inguinal hernia which he had before the operation.

The past few years the reports of most of the successful surgical operations have ended with these words: *the operation was performed with the usual antiseptic precautions*. I shall have to finish this report by adding that the antiseptic method was not employed. But if I do not believe in *ferment* germs, I do believe, and have for the past seventeen years believed, in *contagion* germs. Drs. Tachard, Ducor, and myself took precaution, not only to cleanse our hands before the operation, but to wash them thoroughly in camphorated alcohol. The dressings consisted simply in the application of compresses soaked in camphorated alcohol and water, covered with a piece of sticking-plaster and supported by a body bandage.

A CURIOUS BILL.—Rev. Dr. Robinson, of Paterson, N. J., has sent to the city Clerk the following modest bill for services rendered :

To breaking up the ravages of diphtheria, by showing that it consists of a few ounces of foreign matter in the blood which can only escape through the pores.....	\$1,500
To lowering the death-rate of the city to the extent of 538 lives in two years, by means of circulars, etc., showing what fever consists of...	2,000
To stopping the ravages of small-pox, by showing that 100 cases of it can be expelled from the blood, in two or three hours, by the vigorous action of the pores produced by hot tea...	1,500
Total.....	\$5,000

He adds: "I can prove in any court of justice that I have been the instrument of saving 1,000 lives in this city, without including the thousands whom these discoveries will save in the present generation." It will be seen that the dominie rates the life of the average Patersonian at only five dollars. "Dominie" Robinson is a well-known clerical physician or medical clergyman in Paterson, and although peculiar in some respects, is generally esteemed.

A CASE OF
STENOSIS OF THE RIGHT AURICO-VENTRI-
CULAR OPENING IN CONSEQUENCE OF
FŒTAL ENDOCARDITIS.

A TRANSVERSE CHORDA TENDINEA IN THE LEFT AURICO-
VENTRICULAR OPENING.

By JOSEF KUCHER, M.D.,

NEW YORK.

ALTHOUGH cases of foetal endocarditis are not uncommon, stenosis of the right aurico-ventricular opening is very rare. Rauchfuss (*Entwicklungsfehler am ostium atrio-ventriculare*, Gerhardt, "Handbuch der Kinderkrankheiten," p. 103) found only two similar cases on record, one by Peacock and one by Romberg. In both the aorta and pulmonary artery were normal. In Romberg's case (boy four years of age) the aurico-ventricular opening was very narrow; the tricuspid valves had disappeared. There was no defect in the inter-ventricular septum. In Peacock's case (girl of seven months) the stenosis was not considerable, and was apparently due to synechiæ of the thickened valves, with inflammatory deposits on their outer walls. There were two defects in the inter-ventricular septum.

The present specimen is taken from a child who died twenty-four hours after labor. The mother, a primipara,

strong, healthy, was quite well throughout her entire pregnancy. No history of rheumatism. Labor at the normal term. I had to apply the forceps, when the head was already visible in the vulva, because the pains had almost completely stopped. When the child was born, the chord did not pulsate and was flaccid, and as the child did not cry at once, I was afraid that the application of forceps had been delayed too long. But after having shaken the child a little, it cried lustily and breathed freely. It was a boy, weighing about nine pounds, well formed, except the thorax, which was arched, corresponding to the sternum as in cases of rachitis; but there were no other signs of rachitis. Such an arching (voussure) has been observed in several cases of foetal endocarditis, but it corresponded to the heart-region on the left side of the sternum. The next morning I was told that the child had cried all the night. When I saw it, the face was bluish, the respiration weak, but not superficial as in cases of partially atelectatic lungs; the muscles were flabby, with no tonus in them. I shook it a little, then it began to cry and breathe regularly. Vesicular respiration was distinct all over the lungs. I paid no attention to the heart-sounds. In the evening I was called because the child became cold. On my arrival it was dead. The nurse had seen that the heart of the child palpitated very much before death occurred. From this history, and especially that vesicular respiration was distinct all over the lungs, Dr. L. Conrad and I concluded

that atelectasia pulmonum could not have been the cause of death, and that most likely there must be some congenital defect of the heart.

On post-mortem we found the lungs dark-colored, hyperæmic, everywhere well inflated with air, under the

pulmonary pleura several bloody extravasations. The cut face of the congested lungs discharged reddish serum with bubbles of air. No vernix caseosa or other ingredients of liquor amnii were found in the lungs. The heart was of normal proportions, except the right auricle, which was larger than the left. On opening it, we found the aorta and pulmonary artery with their valves normal, the right aurico-ventricular opening funnel-shaped, with two openings permeable for a Simpson sound at the bottom of the funnel. This change had been brought about by the coalescence of the three curtains of the tricuspid valve, which had been changed into a sclerotic thickened membrane with the two mentioned openings. No inflammatory deposits or other changes were noticeable on the walls of the auricle or ventricle. The inter-ventricular septum was normal. The endocarditis was limited to the curtains of the tricuspid valve, all other valves being normal. In the left aurico-ventricular opening we found a transverse chorda tendinea. The diagnosis of such a chorda was once made by Schroetter on the living subject by its peculiar musical tone, and the diagnosis was confirmed by the post-mortem.

PREHISTORIC SURGERY.—The interesting pamphlet of Dr. Paul Broca describing the trepanned skulls which have been discovered in the caves of France, belonging to the earlier periods of the new stone age, places the date of the first operation of this nature far back in the prehistoric times.

The fact is certain that a great number of these skulls were trepanned during lifetime, probably in infancy and early youth, and that they healed up again, the subject of the operation surviving it for many years. M. Broca supposes this trepanning to have constituted a sacred rite of some sort. For we find that the skulls of these very persons who had undergone the operation in their lifetime were after death subjected again to the same operation. A number of small disks were cut from them in such a way that each disk contained a portion of the cicatrized edge made by the original trepanning. These disks were used as amulets by living persons. But the skull thus treated was in its turn provided with one of these talismanic disks in place of those which had been cut from itself.

It is clear, from M. Paul Broca's descriptions, that this early form of trepanning was performed as an act of mutilation in relation to certain primitive beliefs.

Progress of Medical Science.

ACUTE ENDOCARDITIS LIMITED TO THE RIGHT SIDE OF THE HEART.—Colomiatti (*London Medical Record*, January 15, 1883) describes five cases of acute endocarditis of the tricuspid valve. Having shown that these are not so rare as is supposed, he points out that the affection may fall on the tricuspid or on the pulmonary sigmoid valves only, or on both at the same time; that it may be perforating in one orifice, whilst it is as a vegetation in the other; that it has nothing to do with sex or age, being found in infants, and in youth and old age in both sexes. From a sixth case he infers that endocarditis may affect only the right parietal endocardium, and from their first origin the vegetations may be limited to the right auricular appendage. In all the cases the microscopical examination of the vegetations showed that they consisted of embryonic connective tissue, the elements of which were for the most part in a state of fatty degeneration. The vegetations were very easily torn, and frequently gave origin to pulmonary emboli.

THE ACTIVE PRINCIPLES OF OFFICINAL PODOPHYLLIN.—Continuing his important researches on podophyllin, Dr. V. Podvysotsky, of Dorpat, states that both the root of the *Podophyllum peltatum* and podophyllin (that is, the alcoholic extract of the root) contain a resinous, amorphous, bitter, and very active substance, which the author named podophyllotoxin. This is a mixture of two distinct chemical compounds, called by Dr. Podvysotsky, "picropodophyllin" and "picropodophyllinic acid." As experiments on animals show, both emetic and drastic properties of podophyllin and podophyllotoxin depend exclusively upon their containing picropodophyllin, large doses of which produce vomiting, small ones only purgation. In view of the high price of the preparation of picropodophyllin (which represents the essential active principle of *Podophyllum peltatum*), the author recommends to use podophyllotoxin, best of all in form of an alcoholic solution. While prescribing, it is necessary to take into consideration that this substance is precipitated by an excess of water and by alkalis. When used internally, the remedy begins to act at the end of four hours, or still later; hypodermically, after about two hours. The careful study of clinical results of his own and of other observers, and the experiments made on animals, lead the author to the conclusion that podophyllotoxin is a very useful remedy for constipation, is very comfortably borne by patients, and does not interfere with digestion even when used for a long period. It is indicated especially in chronic constipation in consequence of intestinal atony and sluggishness, in catarrhal icterus, and similar cases. The doses are given as follows: for an adult, from one-fourth to one-third of a grain at a time, from one-half to two-thirds of a grain daily; for a child, from one-one-hundred-and-twentieth to one-twentieth of a grain in each dose; the second dose is to follow not sooner than eight to ten hours after the first. The best preparation for an adult is made by dissolving two grains of podophyllotoxin in two hundred grains of rectified spirit. The dose is thirty drops in a small glass of wine. Alkalis should be avoided during the treatment.—*London Medical Record*, January 15, 1883.

TREATMENT OF ERYSIPELAS BY SUBCUTANEOUS INJECTION OF RESORCIN.—Dr. T. F. Bogusch reports (*London Medical Record*, January 15, 1883) four cases of erysipelas which he successfully treated by hypodermic injections of a five per cent. solution of resorcin. Having marked the margins of redness with ink, he made a number of injections around the whole inflamed region, along the line running outside of the mark, at a distance of about $1\frac{1}{2}$ cm. He used for each injection 0.25 cub.c. of the solution, always directing the needle toward the cen-

tre of the diseased part. As many as sixty-seven, twenty-nine, thirty-six, and seventy injections (at points nearly equally distant) were required in various cases to complete an elevated ring around the affected region, resulting from the blending of individual swellings produced by injections. In all cases the injections completely cut short the further spreading of the inflammatory process, the temperature rapidly falling to the normal level. No untoward symptoms were caused by this treatment, and no other treatment was used.

PATHOGENESIS OF VARICOSE ULCERS.—It is evident enough that varicose ulcers are caused by the presence of varicose veins. But that something further is necessary for their production is shown by the fact that ulcers are not formed in every case, even of marked varicose veins. This second necessary condition has been supposed, by several observers, to be a neuritis in the affected limb. That this supposition is correct, M. Quinn believes to have demonstrated by examination of the nerves of the member. He states that he has always found a neuritis. This could not have been caused by extension of the inflammation from the neighboring tissues, as the portions of nerve examined were taken at a considerable distance from the ulcer. It could not have been an ascending neuritis, as then the sclerosis would have attacked only those nerves whose distribution corresponded to the seat of the ulceration, which he states was not the case. M. Quinn thinks the neuritis is occasioned by varicose dilatation of the veinules passing from the nerve-trunks. This dilatation is accompanied by phlebitis, and the inflammation is quickly propagated to the nerve-sheaths.—*Journal de Médecine de Paris*, December 22, 1882.

CARDIAC HYPERTROPHY CONSECUTIVE TO NEURALGIA OF THE ARM.—Dr. Potain relates several cases in which neuralgia of the left arm, due to traumatism, was followed by hypertrophy of the heart. He explains the occurrence by the nervous connections existing between the cardiac plexus and the brachial plexus, and remarks upon the reverse conditions which obtain in cases of angina pectoris.—*Archives Médicales Belges*, December, 1882.

PLEURISY WITH INTERCURRENT ANASARCA.—Dr. Rossignol relates the case of a cavalryman, twenty-one years of age, who was admitted to hospital, suffering from a slight attack of bronchitis of the larger tubes. He had never had any severe illness. Eight days after admission he was seized with repeated chills, fever, sweating, and pain in the chest. Pleurisy with effusion was developed on the left side. The disease ran its usual course, though somewhat slowly, during a period of five weeks. At that time slight œdema of the feet was noticed, but was attributed to the anæmic condition of the patient, and to slight obstruction to the circulation. On the following day, however, there was another chill with fever and sweating, and on the day succeeding that there was marked general anasarca. The heart was perfectly normal, and there was not the slightest trace of albumen in the urine. The fluid in the chest re-accumulated when the anasarca set in. The œdema gradually disappeared under appropriate treatment, and at the time the report was made (two months later) the patient was nearly well. Dr. Rossignol offers no satisfactory explanation of this curious occurrence.—*Archives Médicales Belges*, December, 1882.

SUBCUTANEOUS INJECTIONS OF CARBOLIC ACID IN MUSCULAR RHEUMATISM.—The results of some investigations recently undertaken by Binz would seem to show that the action of carbolic acid and other so-called antiseptics in preventing suppurative inflammation is due, in great measure at least, to the influence exerted by these substances upon the white blood-corpuscles. In certain experiments upon the mesentery of a frog, this observer ascertained that the migration of the white corpuscles was almost entirely prevented by applications of a very

dilute solution (1 in 1600) of carbolic acid. Led by a consideration of these results Dr. Edgar Kurz, of Florence, instituted some experiments in the treatment of muscular rheumatism by subcutaneous injections of carbolic acid. He reasoned that in this disease we have to do not merely with hyperæmia and serous exudation, but with plastic infiltration of the perimysium and migration of the white corpuscles of the blood. In proof of this assertion he instances the formation of rheumatic nodes in severe cases. This method of treatment was tried in three cases only, but in each the success was stated to have been remarkable. In one case of deltoid rheumatism, marked relief of pain followed within an hour after ten injections of a two per cent. solution. After six injections on the following day the patient was cured. The second case was one of lumbago. The patient had had several previous attacks in which relief was obtained only by morphine. Twelve injections were made in the painful region in the morning. In the afternoon the patient appeared in the doctor's office, complaining only of a slight inconvenience in free movements. The third case was one of rheumatism of the right lower extremity with sciatica. The patient had previously suffered for an entire winter. The present attack was of eight days duration. The patient could with difficulty take a few steps, and suffered severely also at night. The treatment consisted in injections of a two per cent. solution of carbolic acid. At first twelve insertions were made each day, and the number was gradually increased to forty every day or every second day. After the second day the patient was able to stand upright and to walk with tolerable ease. The nights were restful. Fourteen series of injections were made and the patient was entirely relieved of pain. No symptoms of carbolic acid poisoning were observed even when forty insertions were made at one sitting, amounting to 12 minims of carbolic acid. Dr. Kurz states that the injections should be made into the muscle itself, and not immediately beneath the integument. In parts where there is considerable overlying adipose tissue, as in the thigh, he plunges the needle perpendicularly into the limb as far as it will go. No pain is caused by a two per cent. solution, or at most only a very slight burning sensation. Each injection consists of fifteen drops of the solution, containing three-tenths of a minim of carbolic acid.—*Memorabilien*, December 30, 1882.

LOCAL EMPLOYMENT OF BORACIC ACID.—Dr. King relates several cases (*Memorabilien*, December 30, 1882) of the successful employment of boracic acid in affections of the mucous membranes. Four cases of vaginitis of long standing in little girls were promptly relieved by the local application of the remedy. In quite a large number of cases of leucorrhœa, due to cervical catarrh, a cure was effected by tampons of boroglycerine or by boracic acid in powder. In a case of ozœna of forty years' duration considerable relief was obtained by boroglycerine (2 parts in 10) applied on cotton. In several instances of pharyngitis with posterior nasal catarrh the troublesome symptoms rapidly disappeared under treatment by boracic acid in powder.

CONVALLARIA MAIALIS IN HEART DISEASE.—Dr. Berthold Stiller has met with very indifferent success in the treatment of heart disease with convallaria. He reports upon twenty-one cases of various forms of disease, in patients aged from eleven to seventy years. The drug was administered in infusion ($\frac{3}{4}$ –1 to the pint) in tablespoonful doses every two hours. In seventeen of the cases absolutely no results were obtained. In two there was a slight increase in the amount of urine, but no improvement in the other symptoms, and no diminution in the anasarca. Indeed, in one case, the œdema actually increased during the administration of the remedy. In one case of weak heart with general anasarca, a slight improvement was noticed after the convallaria had been taken for twelve days. The pulse was dimin-

ished in frequency and strengthened; the œdema of the scrotum, though not of other parts, subsided, and the patient expressed himself as feeling better. In another case of mitral and aortic insufficiency with general anasarca, digitalis had been taken for some time, during which the symptoms became worse. Convallaria was now given with apparently good result. The dyspnoea was lessened and the excretion of urine increased, but there was no improvement in the irregular action of the heart or in the dropsy. The reporter raises the question, however, whether even this slight amelioration may not have been due to a cumulative action of the digitalis previously administered. From these experiments Dr. Stiller concludes that convallaria, so far from being an efficient substitute for digitalis, is not worthy of even ranking as an adjuvant to this remedy in cardiac disease. He admits, however, that the specimens of convallaria used by him may have been of quality inferior to that employed by other observers, who have reported such brilliant results.—*Wiener Med. Wochenschr.*, November 11 and 18, 1882.

HISTOLOGICAL CHANGES IN THE SKIN IN MEASLES AND SCARLET FEVER.—Neumann states that the principal changes in the skin in these diseases are met with in the glands and blood-vessels. The latter are dilated and surrounded by a round cell proliferation which even accompanies the capillary loops in the papillæ. Similar changes are observed in the sweat-glands, although the surrounding cutaneous tissues are free from the infiltration. About the sebaceous glands the new growth is deposited chiefly at the under part. It never is found within the walls of the glands. The arrector pili muscle is always infiltrated. In scarlet fever the cutis and epidermis also participate in the inflammatory process. Clinically, it is important to remember that this round cell exudation extends even into the horny layer of the epithelium. The epidermis presents numerous cracks and fissures which seem to be filled with round cells and blood-corpuscles. In like manner the cuticular fibres are compressed by the new growth, and in places are dislodged by aneurismal dilatations of the blood-vessels. The contagious properties of the epithelial scales are due, the author believes, to the above-mentioned changes in the epidermis.—*Wiener Med. Wochenschr.*, November 18, 1882.

DOUBLE EXISTENCE.—Dr. Verriest relates the case of a woman who passes her life in two entirely distinct and alternating states. In one of them she can talk, but cannot swallow liquids; in the other she is able to swallow, but is deprived of all power of speech. While in one state she remembers perfectly all that has happened previously in that same state, but is totally oblivious of everything that occurred in the alternating existence. Lately, a third state has developed, the external characteristic of which is a total paralysis of the right leg. All remembrance of this condition is also lost when once the patient has emerged from it.

A similar case has been recorded by Jessen. A young woman fell suddenly into a deep sleep, and upon awakening had lost all memory of past events. She was obliged to relearn to read and write, and to make the acquaintance again of persons with whom she had formerly associated. After a few months she returned to her former condition. Thus she continued to alternate between the two states of existence, the change being always preceded by a deep slumber. Memory was retained only for events happening in the like states, and was lost for the alternating periods. Two other cases of like nature have been reported by Schroeder v. d. Kolk and Azam.—*Deutsche Medicinal-Zeitung*, November 23, 1882.

MUSTARD AND MOLASSES.—Dr. Tyson, of Philadelphia, recommends the addition of molasses to mustard in making plasters. This furnishes a mild persistent counter-irritant which can be worn for hours.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, February 24, 1883.

CEREBRAL LOCALIZATION AND THE PSYCHICAL FUNCTIONS.

WITH regard to the general physiology of the cerebral hemispheres there is little doubt or dispute.

If Hippocrates really taught (what is by no means certain) that the brain is a cold inert gland, of no use but to secrete phlegm and cool the blood, the school founded by him soon promulgated a different doctrine, and one celebrated treatise ("on epilepsy"), attributed by some critics to Hippocrates, but probably of a later date, defines the functions of the cerebrum in a manner which could hardly be improved by any modern, except in the way of amplification and precision. Galen, in the second century of the Christian era, first gave authoritative statement to the doctrine of cerebral physiology which henceforth prevailed for more than fourteen centuries, and which, with some slight modifications of phraseology still holds. Galen had observed cases of paralysis from brain disease, the perturbations of intellect which arise from cerebral inflammations, the abolition of consciousness and volition which follows an apoplectic stroke, and the partial losses in the psychical sphere (amnesia, aphasia, etc.), which commonly attend a return to consciousness after apoplexy.

It can hardly be said that much was added to the sum of knowledge of cerebral physiology taught by Galen, till the modern era of experimentation on animals commenced—an era almost dating with the beginning of this century.

If the physician of the olden times obtained important scientific data respecting brain-function from clinical observation, aided now and then by the autopsy, the phenomena of dementia and mental alienation being also of great suggestive value, his modern successor is able to utilize all these facts, and to greater advantage, since the means of precision have been multiplied, and cerebral physiology has received a powerful reinforcement from comparative neurology.

In accordance with what logicians call the "method of concomitant variations," the physiologist studies the gradations of the brain and nervous system throughout the animal series, and observes like gradations in the powers of mind. The effects of toxic agents and stimuli in altering cerebral function are also noted. By the "method of difference," i.e., removal of *parts* or the *whole* of the hemispheres, more important results still

are gained. Of course it is assumed, as the basis of these investigations, that throughout the entire animal kingdom homology of structure implies homology of function, and that inferences fairly deduced from carefully conducted experimentations, are legitimate inferences.

The only animals that have survived the entire removal of the cerebral hemispheres, so as to be subjects of experiment, are birds and cold-blooded animals. The general characteristics of animals so mutilated are alike in all. Though excito-motor and sensori-motor action (terms for which we are indebted to Dr. Carpenter) remain, ideo-motor and voluntary action are lost. "How admirable!" says Flourens, who must be credited with the first experiment of this kind, "all the organs of sense remain, and all the perceptions are lost."

With the loss of perception, volition, desire, judgment, and memory are lost. Automaticity is at its highest in these animals, the control of whose limbs is little dependent on voluntary acquisition, all the faculties and functions except the most psychical being fully developed in them at birth, and co-ordinated in the sensori-motor and spinal centres; consequently destruction of the cortical centres does not cause that paralysis of movement which is noticed (more or less permanently) in all animals higher in the scale of development. Such, at least, is Ferrier's explanation of that retention of motricity which succeeds the mutilation.

If it were possible in a human being to remove the cerebral hemispheres, and not produce such a shock as to cause immediate death; if the individual could survive such an operation as does the pigeon, we should undoubtedly witness a man reduced to the state of an automaton, without desire, without emotion, without perception, without volition. Nature does, in fact, produce the experiment for us, although the lesions are far more complex than those above described. There is a form of melancholia called by Baillarger, Ball, Etoc-Demazy, and others, *stupor*, whose material lesions produce suspension (by pressure) of the functions of the cortex, and whose psychological accompaniment is absence more or less complete, as the lesion is more or less general, of all mental manifestation. In pronounced cases the subject is listless, emotionless, and unconscious—remains fixed to one spot (like Flourens's bird), and seems as if deprived of his special senses. The characteristic lesion of this form of mental alienation, according to Etoc-Demazy, is œdema of the convolutions. In marked cases of general paralysis of the insane, intelligence and general motility are extinguished, anæsthesia and analgesia are complete; a dementia of the most absolute and hopeless kind exists. The autopsy always reveals, as the essential lesion, atrophy of the cortical layers of the hemispheres. The living protoplasmic elements are choked out and perish by reason of excessive development and thickening of the meninges and neuroglia. Dementia is acquired idiocy, and is always due to destructive lesions of the cortex; idiocy is due to congenital arrest of development of the cortex.

Hence we see that grave lesions of the encephalon, whether morbid or artificial (the result of experiment), are attended with enfeeblement or disappearance of the most noble psychical qualities, and that motricity also suffers in a marked degree. Whether there be distinct

psychical centres (as the phrenologists taught), or whether those portions of the cortex which are peculiarly the seat of mind act as a unit, so that *all* participate in feeling, volition, perception, etc., as Flourens believed, is not absolutely determined. The supposition that the brain "acts as a whole" (so far as the purely psychical operations are concerned), is quite in harmony with the results obtained by a gradual slicing away of the cerebral lobes, as performed by Flourens, Vulpian, and others, on pigeons. It also agrees with the results of lesions, as gunshot wounds, abscesses, etc., in the frontal regions in man, as well as with that integrity of consciousness which often attends complete hemiplegia when one hemisphere is extensively damaged. Goltz, who denies cerebral localizations altogether, believes that every portion of the cortex (those supposed to pertain to motricity, as well as others) is in relation with every function exercised by the hemispheres. His views are thus in harmony with those of Flourens and those of Brown-Sequard.

SIR WILLIAM THOMPSON ON THE SIXTH SENSE.

It is announced that the distinguished physicist, Sir William Thompson, ascribes to man six senses, namely, those of *force*, heat, sound, light, taste, and smell.

We apprehend that this announcement comes rather late in the day, as American text-books have for some time past taught this doctrine. As an instance we may mention "The Human Body," by Dr. H. Newell Martin, of the Johns Hopkins University, published in 1881. In this work Dr. Martin states, "We commonly distinguish five senses, those of sight, sound, touch, taste, and smell," and he then suggests that "temperature" should be added.

It will be noticed that both authors claim for man the possession of six senses, Sir William Thompson substituting "force" as a sense, for "touch."

Physiologists are indebted to the science of physics for an explanation of many facts which would otherwise baffle research, but we fear that the present excursion of Sir William Thompson into the domain of physiology will not prove a success.

A physicist describes "*force*" as being any action between two bodies, which changes or tends to change their relative condition, as to rest or motion, or, more generally, which changes or tends to change any physical relation between them. Our readers must not confound "*force*" with "power," the latter word having relation only to the work to be done.

It is difficult to read this definition of "force" and at the same time class it as a human sense, or to discover the sense organ involved. Our sense organs have a special relation to some one form of "*force*" or energy, but that "*force*" is external to the body, and acts merely as an irritant to excite our sensory nerves, and some organ is necessary for generating this nervous impulse. Where, may we ask, is the organ of force?

Unless Sir William Thompson considers that "*force*" is synonymous with "*touch*," it is incomprehensible how he can omit "touch" from the list of our senses. The organs of "*touch*," or the nerve-end organs in or immediately beneath the skin, have been described often enough, and, from an evolution point of view, touch is the first

distinctly differentiated sensation, and this primary position it still largely holds in our mental life; a man who could see but had no touch sense, would conceive solid objects very differently from the rest of mankind.

The delicacy of the tactile sense shows it to be one of the most valuable of our senses. For instance, we believe that a weight of .03 grain pressing on an area of .0139 square inch can be distinctly felt in the back of the fore-arm, and that on the front of the fore-arm .036 grain can be similarly felt.

Doubtless, muscular sensations are often combined with proper tactile sense, and moreover, temperature sensations are also involved, thus *pure* tactile feeling is rare.

Tactile and temperature feelings are ordinarily so very different, that we can no more compare them than luminous and auditory sensations, but we are aware that some persons maintain that they are identical. In favor, however, of the view that touch and temperature are sensations of distinct modality, with different end organs, nerve-fibres and brain-centres, several weighty facts can be produced. The regions of most acute discrimination for each sensation are different, and cases of disease are recorded in which persons have been extremely sensitive to variations in temperature, while their tactile sensibility was unaltered; and conversely, cases in which the patient could feel that he had been touched, but was unable to say whether with a hot or cold object.

It is impossible to do justice to this subject in the space at our command, but perhaps sufficient evidence has been given to show the necessity of withholding assent to Sir William Thompson's assertion, that "*force*," which is a form of motion, should be classed as a human sense.

THE PROTECTION OF COLLEGE STUDENTS FROM VENEREAL DISEASES.

PHYSICIANS living in college towns or in provincial cities near institutions of learning, not infrequently find themselves invaded by bands of students who are suffering from various forms of venereal disease. The history of the case generally is that these young men go off on a "frolic" to some neighboring place, get to drinking, and end their exuberance in some cheap brothel. Few escape becoming infected with venereal disease in some shape. This they are apt to neglect, or, at least, they fail to secure the best treatment, and serious results thus ensue.

There are certain reasons why especial attention deserves to be paid to the facts above stated. The young men or boys who enter college have as yet neither habits formed nor character matured. The social life fosters the natural exuberance of spirits, and opportunities to work them off are gladly seized. There is often considerable pride felt by these amateur men in being a little bad. It is very easy to go from one step to another, and end a sportive night with a dispenser of syphilis.

This thing is done with little knowledge of the physical—to say nothing of the moral—dangers which are encountered. With a class, therefore, peculiarly exposed and peculiarly susceptible to temptation, it is but right that some special care should be taken.

We urge it upon college faculties, therefore, to consider these special dangers to which their students are

intrusted. Let them inculcate directly, and not in spiritual generalities, the fact that the truer manliness lies in self-restraint and continence. If such appeals have no force, the real dangers should be portrayed; finally, it is but right that the erring but more or less noble victims of indulgence should be able to reach competent medical men. In some places this is not possible.

THE SUCCESSFUL TREATMENT OF EXTRA-UTERINE PREGNANCY.

THE interesting and important article in our last issue entitled "The Successful Treatment of Extra-Uterine Pregnancy," by Dr. A. D. Rockwell, has called forth numerous inquiries, and we take this method of answering them in a general way. Formerly, as is well known, these cases resulted either in immediate death through rupture of the distended tube, or in protracted suffering, with frequently a fatal ending, through the efforts of nature, to rid itself of the foetal mass. The only other alternative was the knife, with its attendant dangers.

The method described by Dr. Rockwell, on the contrary, and used with such uniform success, cannot but commend itself to the profession everywhere, and especially, as it is simple in its details, certain in its results, and attended with but comparatively little suffering or danger to the mother. We observe in this communication, however, one word of caution in the performance of the operation, which may well be emphasized, and this is, the possible danger, in cases well advanced, of rupturing the sac by too powerful, or injudicious applications. We can readily believe that this is a possible complication, but the total of cases reported is as yet too few for ultimate conclusions. Up to the second month there can be but little, if any danger, but, unfortunately, the pregnancy often advances considerably beyond this period, before its seat is discovered. Nature is not always a "kind mother," but in these cases there can be no question of her generous aid. It would seem that she supplemented the efforts of art by first encysting and then gradually absorbing the offending material.

THE IMPRESSIONIST SYSTEM IN MEDICINE.

WE have received, from an esteemed contributor in Ohio, the following letter:

"DEAR SIR: For the last three years I have been giving to my typhoid fever patients muriatic acid, with excellent results. The symptoms of meteorism and diarrhoea have appeared to be much less prominent. There have been fewer pulmonary complications also, and I believe that the mortality has been lighter, and that the patients have passed through the disease with fewer bad symptoms generally. My impression is, also, that the duration of the fever has been shortened. I have not notes of all my cases, but I am so convinced of the value of this acid that I venture to call the attention of your many readers to an old but somewhat neglected remedy. Yours, etc."

We publish this letter, for it illustrates so well the faulty and valueless system of reaching conclusions used by so many American physicians. Medicine is not an exact science, but so much the more is it necessary to use every possible means to make it such. We consider

the observations of our correspondent as of no use whatever. His conclusions are only impressions; the numerous factors which enter into the etiology and pathology of typhoid fever are not considered. The number of cases is not given, nor the age, or sex, or character of epidemic, if there was any.

Many a doctor, in treating disease, gives a certain remedy with apparently excellent result. Immediately he feels confident in his new drug; his views of subsequent cases are colored by his enthusiasm over a single success. His therapeutic method for years, in particular diseases, turns upon the happy ending of the first few cases. He is the victim of a rose-colored "impression."

This constitutes what we choose to call "the impressionist system in medicine." It is now and always has been the bane of therapeutical science. We have fashions in medicine, because fancy, more than exact method, so often determines what drug we shall use.

It would be well if some one could define for medical men the sources of error in reaching therapeutic truths, the minimum test which a drug must undergo in order to take rank as a remedy. This has been done in a certain indefinite way for some diseases, but we need more careful and extended determinations.

The impressionist method is very well in art, which interprets nature from an emotional standpoint, but only exact observation and careful deduction are allowable in medicine, which at least strives to be a science.

THE THIRD CORPUSCLE OF THE BLOOD.

DR. NORRIS, of London, in his book on "The Physiology and Pathology of the Blood," claims to have discovered a third or invisible corpuscle of the blood, which he regards as identical with the hæmatoblasts of Hayem and the small blood-plates of Bizzozero. The soundness of his theory rests entirely on the demonstration of the presence of the invisible corpuscle as a normal element of the blood. He claims that he has made this satisfactorily, and gives in evidence a large series of photographs which illustrate his views.

A "criticism and refutation" of Dr. Norris's theories regarding this body has been published by Mrs. Ernest Hart, of London, in which the writer claims that Dr. Norris's conclusions are based upon "illusions engendered by his peculiar methods of working," and reviews the successive steps in his processes with a keenness which is both searching and interesting.

Evidently Dr. Norris's critic is not a novice, for everywhere a familiarity with the action of reagents and the influence of mechanical conditions is shown that speaks of practical manipulation and study, and therefore the physiologist and the histologist must give her work careful scientific attention. The pamphlet also tells us that this is not the first time its author has criticised Dr. Norris's work, and in order that the reader may understand exactly upon what the controversy centres it will now be necessary to state briefly the view held by that author. He describes what he calls the "advanced lymph-disk," somewhat smaller than the red disk, colorless, transparent, and homogeneous, and states that it is found in the lymph-glands, is present in larger numbers in the thoracic duct, and is incapable of being seen in the

blood because it has the same refractive index as the liquor sanguinis, and has not become colored by endogenous secretion of hæmoglobin. These bodies, says Norris, are the nuclei of the uninucleated corpuscles seen in such abundance in the lymph and blood-forming organs, which, either while remaining in the gland or during their passage through the thoracic duct, shed their close-fitting, granular cell-wall. When colored they are visible, and are then seen as red blood-corpuscles.

Certainly this is an ingenious theory, and we share in the "genuine regret" expressed by the writer of the criticism, that any one should feel forced to conclude that it is based upon error in observation. We also share in the belief that only the most diligent investigation, conducted by the most conservative methods can place such a theory upon a solid basis, "so delicate and unstable are the blood-corpuscles, so careful and exact must be the conditions under which they are examined after quitting the vessels, and so guarded and cautious must be the deductions drawn from appearances presented under the microscope." All these conditions seem to have been fully appreciated, and their influence carefully estimated by Mrs. Hart. The effect produced upon the corpuscles by pressure between two glass surfaces bound firmly together, the question whether all red corpuscles lose their hæmoglobin in an equal ratio, whether there is any difference in the quality of these bodies, the effect produced by solutions having a different refractive index, points bearing directly on the question at issue, have been considered closely, and the sources of error eliminated so carefully, the reader is led to the conclusion that Dr. Norris's theory has been shivered to a degree which will render it difficult to collect the fragments.

News of the Week.

TENEMENT-HOUSE CIGARS.—The bill before the State Senate to prevent the manufacture of cigars in tenement-houses, or in apartments occupied as dwellings, has been ordered to a third reading without opposition. Mr. Covert made a statement that several authentic cases had occurred of serious diseases having been communicated to smokers of tenement-house made cigars, and the cigar-smoking Senators, who comprise a large majority of the thirty-two, immediately gave their adhesion to the bill, in spite of the certificate of the Board of Health that there was nothing dangerous or detrimental to health in the business of tenement-house cigar manufacturing.

A MUTUAL AUTOPSY SOCIETY.—Our esteemed contemporary, the *Philadelphia Medical and Surgical Reporter*, refers to the fact that Gambetta belonged to the Société d'Autopsie Mutuelle, and urges the formation of similar societies in this country. Such an organization has existed for some time in New York City.

A CHAIR OF LARYNGOLOGY has been established in the Royal University of Rome, and Dr. Zawerthal has been appointed to fill it.

AN EPIDEMIC RESEMBLING CHOLERA has been prevailing in Waterbury, Conn. It has affected hundreds of people. The cause is not yet known.

THE LOUISVILLE MEDICAL NEWS comes to us without its brown cover and enlarged to sixteen pages.

THE CHICAGO MEDICAL REVIEW has become *The Weekly Medical Review*, and is published simultaneously at Chicago and St. Louis.

THE PHYSICIAN AND THE DRUGGIST—A MEDICO-LEGAL DECISION.—About a year ago Martin McIntyre, a Fonda, N. Y., druggist, put up a prescription for John Cook, written by a Dr. Parsons, of Fultonville. The medicine nearly killed Cook. The physician claimed that the prescription had been altered, and commenced an action against the druggist for damages. The prescription called for one drachm of podophyllin. Dr. Parsons claimed he had written it one grain, and that it had been altered by the druggist to cover up his mistake. The case was tried recently. On the trial McIntyre swore the prescription had not been altered and Dr. Parsons swore it had. Two experts testified that no alteration had been made. Another question in the case was whether or not the druggist was justified in putting up a prescription in which he noticed a dangerous excess of any ingredient. Judge Landen ruled that if the prescription of a regular practising physician is put up as written, the druggist is not responsible. The jury decided that the prescription had not been altered, and therefore no cause for action.

REGULATING MEDICAL PRACTICE IN MICHIGAN.—The Michigan State Board of Health, at its recent meeting, passed the following resolution: That an examination should be required of all who are to practise medicine in this State, as to their qualifications. That such examinations should be restricted to questions in demonstrable knowledge as distinguished from questions of mere opinion.

AMERICAN PUBLIC HEALTH ASSOCIATION.—A meeting of the Executive Committee of the American Public Health Association was held in Washington, D. C., on Friday, the 16th inst. The business before the Committee was the arrangement of the programme for the next annual meeting of the Association to be held in Detroit next fall—October or November, as the Committee decides.

The committee is composed of Drs. E. M. Hunt, President of the Association; Albert L. Gihon, James E. Reeves, J. Berrian Lindsley, Azel Ames, John S. Billings, G. P. Conn, Thomas J. Turner, J. J. Speed, Thomas L. Neal, H. D. Fraser.

THE LIBRARY OF THE LATE DR. GEO. M. BEARD.—We learn that the library of the late Dr. Geo. M. Beard is being catalogued, with a view to disposal by auction.

MORE ABOUT BROKEN THERMOMETERS.—The subject, "broken thermometers," has developed into an important branch of the general department of fractures, and will soon have a literature of its own. We continue to receive communications upon the subject.

Dr. G. M. Kells, of Cincinnati, O., says that a better plan than any yet recommended to save thermometers is the following: "Take any ordinary thermometer case (the wooden ones are the best for the purpose), throw around it a piece of wire just below the junction of the top and body of the case, and twist it tight, leaving an eye on the end of the wire. To this eye attach a chain

about four inches long and secure to the vest with a small pin, the thermometer to be carried in the upper vest pocket."

Dr. Z. T. Dellenbaugh, of Cleveland, O., suggests a plan which must certainly be very effective. He writes: "Having a metal case with enough loose wool in each end to hold the thermometer rather firm; and having procured a rather heavy piece of corrugated, preferably, or plain white rubber tubing one inch longer than the case, it is cut in two pieces at a point corresponding to the screw-joint of the case, so that each piece is one-half inch longer than the part of the case it is designed to cover. Wet the tubing and slip the case in, noting that the rubber projects one-half inch beyond each end of the case. This rarely ever falls out of the vest pocket; should it, the protection the rubber affords is almost certain to save the instrument."

Dr. C. Irving Fisher, of Holbrook, Mass., writes that he has always been lucky with thermometers, and ascribes it to the fact that he buys short ones with metallic cases. Over each end of the case he slips a six-sided rubber tip, such as are used on lead pencils. This prevents slipping from the pocket.

REMOVAL OF A BEAN PIECEMEAL FROM THE EAR.—Dr. T. Y. Sutphen, of Newark, N. J., sends us an account of a case illustrating the difficulties and accidents in removing foreign bodies from the external auditory meatus. A boy, eight years old, was brought to Dr. S. with a common white bean in his ear, which he had placed there two weeks before. Attempts had been made by others to remove the body by the use of the syringe and instruments. These had only resulted in injuring the canal, which was swollen so as to hide the bean from sight. There was a muco-purulent discharge from the ear. The boy was etherized, and an attempt was made to remove the body with a syringe, but it failed. The ear was then syringed with warm water, for four days, which reduced the swelling somewhat. The bean could be seen, and was immovably impacted. With a lance-shaped paracentesis needle, the bean was broken up, with the help of a bent probe, and removed.

THE MEDICAL LIBRARY OF THE LATE DR. J. FOSTER JENKINS, of Yonkers, N. Y., was sold at auction last week. There were one thousand eight hundred lots and about four thousand volumes, not including miscellaneous pamphlets. The library was particularly rich in the literature of obstetric medicine and surgery, from the end of the fifteenth century to the present day. All the specialties were represented, even to atlases and bibliography. A large number of works in black letter, rubric, and some MSS. brought high prices, while some books out of print were sold astonishingly low. Aside from the large purchases of dealers, several public libraries of Boston, Washington, and New York secured handsome additions. Some private libraries in this city will be enriched chiefly from the special departments of medical literature. The collection is said to have cost its late owner \$12,000. The proceeds of sale were about \$4,000.

AN ARMY MEDICAL EXAMINING BOARD TO MEET IN NEW YORK.—An Army Medical Board has been ordered to assemble at the Army Building, corner of Houston and Greene Streets, New York City, March 1,

1883, for the examination of such persons as may be properly invited to present themselves before it as candidates for appointment in the Medical Corps of the Army, and will probably continue in session about three months.

All candidates for appointment in the Medical Corps must apply to the Secretary of War for an invitation to appear for examination. The application must be in the handwriting of the applicant, must state date and place of his birth, and place and State of which he is a permanent resident, and must be accompanied by certificates based on personal acquaintance from at least two persons of repute as to citizenship, character, and moral habits; testimonials as to professional standing from Professors of the Medical College at which they graduated, should also accompany the application, if they can be obtained. The candidate must be between twenty-one and twenty-eight years of age (without any exceptions), and a graduate of a Regular Medical College, evidence of which, his Diploma, must be submitted to the Board.

Further information regarding these examinations, and the nature thereof, can be obtained by addressing the Surgeon-General of the United States Army, Washington, D. C.

POISONING FROM THE PRESCRIPTION OF A CLERGYMAN.—Clergymen are very fond of dabbling in physic. This sometimes leads to serious consequences. The Rev. Mr. Timins, of West Malling, England, has just been committed for trial on a charge of manslaughter. The reverend gentleman appears to have been in the habit of prescribing gratuitously for the members of his flock on the strength of a short period of medical study nearly half a century ago. On the present occasion he administered a spoonful of the essential oil of bitter almonds to a young girl for some supposed complaint, and she died in his arms in a few minutes. His intentions were doubtless good, and it is pitiable to see a clergyman of hitherto unblemished character, and sixty-nine years of age, in such a position. Still zeal, untempered by knowledge, is not of much avail in the practice of medicine. Clerical minds have been too apt to busy themselves with the mysteries of medicine, and let us hope that the unfortunate position in which Mr. Timins now finds himself, may serve as a warning to others of his profession.

SMALL-POX AND THE IMMIGRANTS.—The Health Officer of the Port of New York reports that among the 300,000 immigrants landed in Castle Garden during the last eight months, not a single case of small-pox has been discovered.

GOVERNOR BUTLER AND THE MASSACHUSETTS BOARD OF HEALTH, LUNACY, AND CHARITY.—Governor Butler is credited with the intention to recommend to the Legislature of Massachusetts the abolition of the State Board of Health, Lunacy, and Charity, on the ground of expense, mismanagement, and practical inefficiency.

WOMEN PHARMACISTS.—A systematic attempt to educate women as pharmacists has been initiated in Louisville, Ky. The Academy of Pharmacy opens on March 1st with a class of women students. The Academy has received the gift of a laboratory and a botanic garden.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, January 24, 1883.

GEO. F. SHRADY, M.D., PRESIDENT, IN THE CHAIR.

PRIMARY CARCINOMA OF THE LUNG.

DR. E. G. JANEWAY presented a specimen removed from the body of a man fifty-six years of age. The clinical history was peculiar in the fact that patient's mother was the only relative who had had cancer, and that was an epithelial cancer which had been removed from the lip a number of years previous to her death, and the disease did not return. The patient began to complain, about one year before death, of not feeling well, but no marked complaint was made until about six months previous to death. His history was that of progressive failure of strength and flesh, a very slight febrile movement toward the latter part of his life particularly, 100° F. being the highest, pain in the right side from the beginning, and afterward some shortness of breath upon exertion. Dr. Janeway saw him about seven weeks before his death, and learned that of late the pain in the side had increased in severity. He found flatness over one-half of the right lung, a distinct friction sound over the upper part, with breathing somewhat bronchial and vocal fremitus impaired, and enfeebled and absent respiratory murmur over the lower part. The line of flatness was nearly horizontal. A hypodermic syringe was introduced, and only a very small quantity of bloody serum could be withdrawn. His presumable diagnosis, leaving it for demonstration at another visit, was cancer of the lung, and besides he thought it possible that a malignant process back of it involved the pleura. At his second visit he found no marked change in the physical signs. Exhaustion was increasing, there was no marked febrile movement, no renal trouble, and, by exclusion, he reached the diagnosis of cancer of the lung, perhaps of primary origin. At that time the patient complained of some disgust for food, but there was no special difficulty in swallowing, although he preferred liquids. He expectorated a slight quantity of mucus, which apparently came entirely from the throat. There was no bloody expectoration. The patient suffered markedly from dyspnoea on very slight exertion, and finally died from exhaustion.

The left side of the chest was normal, excepting a slight bronchitis, and this was the only abnormal condition found at the autopsy.

The specimen presented consisted of two parts: first, the right lung, in which the new growth involved the middle and lower lobes; and second, a mediastinal growth. There was no enlargement of glands above the clavicles. In the lung the neoplasm showed itself in the form of an infiltrated cancer, with nodular outgrowths taking up the pulmonary tissue entirely, especially at the peripheral part. The lung was separated from the diaphragm by a layer of fluid one inch and a half in depth, but the diaphragm was normal except where it was covered by a very slight fibrinous deposit. The mediastinal tumor consisted of a mass of enlarged glands at the root of the trachea. In this apparently uniform tumor the new growth had undergone considerable fatty degeneration. In the lung the new growth encircled the bronchi, and crowded their walls from without inward, so that they were apparently filled. There was a pin-head new growth in the lower part of the right lobe of the liver. All the other parts of the body, including the œsophagus, were normal.

From the history of the case and the appearance of the specimen, Dr. Janeway believed that the primary growth was in the lung, and that the mediastinal tumor was secondary. Microscopical examination showed alveoli of medium and large size, containing small polygonal epithelial mono- and bi-nucleated cells.

This was the fourth specimen of primary cancer of the lung which he had seen. In one case he made the diagnosis of carcinoma of the lung ten months before death, and at that time there was no other trace of the disease in the body, but at two months before death carcinoma began in the left breast, and at the time of death the latter growth had reached considerable size. In that case there was no mediastinal tumor, but there were secondary nodules in the liver and right lung. The patient's father died of carcinoma of the stomach, and a cousin had lympho-sarcoma of the pleura.

In the third case it had been supposed that the patient had pleurisy, but the autopsy revealed primary colloid carcinoma of the entire lung. The lung and the liver were the only organs involved.

DISSECTING METRITIS.

DR. H. J. GARRIGUES presented three specimens, all obtained at the Maternity Hospital. About three months ago he exhibited a specimen to the society, illustrating this pathological lesion, and then stated that he regarded it as a rare disease. Since that time he had been able to find the records of two cases. Even in special works on the pathology of the female sexual organs no reference whatever has been made to such cases. Besides, he had asked a large number of physicians, whom he had met, if they had observed loose bodies in the womb after confinement, but all of them had answered in the negative. Nevertheless, he began to surmise that the disease was not so rare as might be inferred from the literature of the subject.

The first specimen presented was derived from a primiparous woman, eighteen years of age. There had been a low forceps operation, very simple in character. She did not seem to be seriously ill at any time; her highest temperature was only 102° F. At no time was there any fetid discharge, and no uterine treatment was instituted. On the thirteenth day after delivery she expelled a cylindrical body which was six centimetres in length by two and a half in width.

The second specimen was also removed from a primiparous woman, eighteen years of age, and in this case there were extensive diphtheritic patches on the vaginal wall and cervix. Her highest temperature was 102.5° F., and that only once. On the eighteenth day after delivery, when she was apparently entirely recovered from her labor, she expelled from the vagina a body six centimetres in length and three and a half in width, and one and three-tenths centimetres in thickness.

The third specimen was from a patient twenty-nine years of age, in whom there was retention of placenta. The placenta was removed, artificially, one hour and three-fourths after delivery, and was composed of two parts joined by membrane. This patient had a high temperature, 103.5° F., and, besides, the lochial discharge was fetid and almost constant. The uterus was washed out with a two per cent. solution of carbolic acid two or three times a day. She was comparatively well, although there was constantly some indication of slight septicæmic condition until, on the seventeenth day after delivery, she expelled from the vagina a body which was twenty centimetres long and thirteen wide, and of variable thickness. The house physician stated that it was one inch thick in some places when first expelled.

Dr. Garrigues remarked that some little time ago a specimen was presented to the society for a candidate, which he had always believed was of the same character. These, together with two cases reported by Russian physicians, made seven in all. He believed that they were diphtheritic in character. In two out of his four cases, there was pronounced diphtheritic inflammation. In the others there was not sufficient disturbance to lead to a vaginal examination. How these large bodies are thrown off he had been able to understand by the study of another condition, in which the change was simply diphtheritic. In that case there was pronounced metritis, the

wall of the uterus measured from one to two inches in thickness, and there was diphtheritic membrane on the cervical mucous membrane, and in the interior of the body of the womb, around the opening of one of the Fallopian tubes. On the other side there was a patch of diphtheritic membrane of the size of a three-cent piece, and from this small patch he was able to follow a similar yellowish formation coming out of the external part of the uterus so as to form a layer just below the perineum. Associating the thickening of the uterine wall and this yellow mass extending in two directions, he was able to understand how it was possible that such pieces can be thrown off from the uterus. He did not regard the process as especially unfavorable. There is this danger, however, that if the person again becomes pregnant, there is likelihood that rupture of the uterus may occur during labor.

DR. J. C. PETERS remarked, that in the last volume of the "Transactions of the Edinburgh Obstetrical Society," a series of such cases were reported, and were spoken of as positive sloughs. So far as he recollected, however, almost all the patients recovered. He thought it probable that they belonged to the same class of cases described by Dr. Garrigues.

DR. GARRIGUES thought that his cases could not be regarded as those in which sloughing had occurred, because there was not the least fetid odor to the discharge, except in the last one.

THE PRESIDENT said, that in the specimen presented for a candidate, and referred to by Dr. Garrigues, the body expelled was several inches in length, about an inch in width, and contained smooth muscular fibre in its substance. There being some question as to the structure of the mass, it was examined by a distinguished gynecologist, who presented it at a meeting of the New York Obstetrical Society, and asserted that it was composed mostly of striated muscular fibre, with the conclusion that it might possibly be the muscular fibre of the heart of a monster, the heart being the only portion remaining within the uterus.

DR. JANEWAY said that small polypi might exist in the pregnant uterus, become detached during the progress of labor, and appear subsequently in the discharges. He thought that a true dissecting metritis was a serious process. In several instances, at post-mortem examinations, he had found evidence that a septic fluid from an inflamed uterine mucous membrane had found its way into the blood-vessels, and led to the formation of a thrombus in the vena cava, and he had been led to believe that it was not a process which terminated in recovery in very many cases.

DR. BOZEMAN thought the explanation given by Dr. Janeway was very satisfactory, concerning the formation of some of these growths, and referred to a specimen, already presented to the society, of a myo-fibroma expelled from the cavity of the uterus. A miscarriage took place, and six weeks subsequently a body of considerable size was thrown off.

DR. GARRIGUES thought that the explanation offered by Dr. Janeway was very ingenious, and perhaps would apply to two of the specimens which he had presented. He thought, however, that it would not apply to the third case because the shape and size of the mass was unlike that of a polypus. Neither did he think it would apply to the specimen presented by the president in behalf of a candidate, because in that instance the substance expelled was a sheet-like piece of membrane, several inches in length, and only of slight thickness and considerable width. In reply to a question, Dr. Garrigues said that he was able to prove the existence of diphtheritic infection in two of his cases, and inferred that it existed in the others.

DR. JANEWAY remarked that he had seen two cases in which there was complete exfoliation of the mucous membrane of the bladder. In one instance it was discharged before death, giving rise to a condition closely

resembling labor, and in the other he found a cast of the bladder at the autopsy. The lesion was regarded as a croupous inflammation of the bladder.

DR. PEABODY had seen one such specimen in the bladder of the horse.

DR. GARRIGUES believed that it could be proved that his specimens were not mucous membrane, because there was no trace whatever of glandular structure. He had seen only one case of shedding of the mucous membrane of the uterus, and that was in the practice of Dr. Jacobi.

DR. BOZEMAN had seen a case of what he termed ulceration of the bladder, in which nearly the entire mucous membrane was thrown off. In that case there was very great hypertrophy of the muscular coat of the bladder, the wall of the organ being three-fourths of an inch in thickness. He made an opening into the vesicovaginal septum about the size of a half-dollar, and the patient was relieved of the tenesmus and other symptoms, and went on very well for two or three weeks when the opening closed, and he was obliged to make another and increase it nearly to the size of a silver dollar. After the second opening was made he was able to explore the bladder completely with the finger, and was also able, placing the patient in the knee-elbow position, to see, by the aid of reflected light, the entire inner surface of the bladder and found that it was denuded of its mucous membrane. The progress of the case after the second operation was satisfactory, the muscular coat gradually became thinner and softer, and after six or eight months he performed an operation for closure of the fistulous opening, but it was subsequently demonstrated that the cure had not been complete. The former symptoms again developed, the bladder was again opened, and the patient was allowed to go six or eight months longer. In the meantime her general health improved. Subsequently an operation was performed for closure of the fistulous opening, and the cure was complete with a perfect reproduction of the mucous membrane. He thought the condition resulted from an ordinary attack of cystitis, and believed that it was the only one of a similar character on record.

DR. G. L. PEABODY presented a specimen of

SARCOMA OF THE RIGHT OPTIC NERVE.

The patient was in the New York Hospital about two weeks, and complained of general malaise, loss of appetite, inability to work and sleep. He went on into a condition of apathy, which lasted for ten days, and then symptoms of cerebral disturbance became well pronounced. He died with a diagnosis of meningitis, based upon the clinical history. At the autopsy, there was found meningitis and intense congestion, and there were two small deposits of pus, neither of which was large enough to make him sure of their existence from examination with the naked eye. Besides, he found a small tumor upon the right optic nerve about half the size of a small French pea. The tumefaction upon the optic nerve was largely fibrous in character, but between the fibres of the optic nerve itself was a dense layer of small round cells, and ascending between them in this stroma were large blood-vessels filled with blood. The interpretation which he gave to the case was that the sarcomatous tumor developed on the optic nerve and caused meningitis. It probably had existed for some time, but was too small to produce physical evidence of its presence.

DR. JANEWAY said that he had seen a little larger tumor than this produce similar trouble in a case brought to him by Dr. Maxwell. An oculist had operated upon the patient for internal strabismus. Shortly afterward the patient died of general paralysis. At the autopsy there was found a small sarcoma, not larger than half a split pea, which pressed upon the sixth nerve and led to softening of the pons, and in that way caused death. The paralysis of the ocular muscle was due to

the pressure, but death occurred from acute softening of the pons. He had also had another case, in which a small tumor pressed upon the cervical dura and gave rise to symptoms of acute meningitis. Of course, in meningitis it was necessary to think of the various sources of possible origin. In one case lately, he had found well-marked otitis media purulenta without symptoms during life, and it had doubtless given rise to meningitis. In a second case, one of ordinary typical cerebro-spinal meningitis, there was well-marked otitis media purulenta.

DR. PEABODY said he had observed the same thing, and had found in acute cerebro-spinal meningitis, otitis media purulenta where there was no suspicion during life of ear trouble.

DR. J. L. SMITH remarked that it was a well-established fact that in cerebro-spinal meningitis, if the disease continued for some time, inflammation of the middle ear is liable to be developed.

DR. T. E. SATTERTHWAITE presented specimens as follows :

ABSCESS OF THE LEFT SUPERIOR MAXILLA—OPERATION
—EMBOLIC PNEUMONIA AND HEPATITIS.

Post-mortem examination of Dr. George M. Beard, January 24, 1883, at 3.15 P.M., death having occurred on the previous day at 10.30 A.M.

Present at the examination, Drs. J. L. Little, J. R. Leaming, T. H. Kellogg, G. H. Mitchell, D. H. Goodwillie, W. H. Porter, J. A. Hegeman, Charles L. Dana, J. Messenger, and T. E. Satterthwaite.

The following account of his illness was furnished by the physicians who had him under charge.

On Thursday, January 18, 1883, about 10 A.M., Dr. Beard called at the office of Dr. D. H. Goodwillie. He was then suffering from an infra orbital neuralgia of the left side; his face was swollen, and his left eye congested; both pupils were much contracted; there was also stenosis of the left nostril, pus and mucus passing down from the left posterior nares into the pharynx. The root of the left second superior bicuspid had an amalgam feeling in it, and at its apex was a maxillary abscess having no communication with the mouth. Under an anæsthetic the bicuspid root was extracted, and the abscess trephined through the external alveolus. A good deal of pus escaped. It was now found that the maxillary abscess communicated with the left nostril. Dr. Beard was again seen at his rooms about 3.15 P.M., by Dr. Goodwillie. Dr. T. H. Kellogg was found in attendance, having been summoned by Dr. Beard, and visited him at 2.30 P.M. Dr. Beard was then recovering from a prolonged chill. Dr. Kellogg had found the patient sitting dressed on the sofa, but in evident distress. Antipyretics and stimulants were immediately ordered, and this treatment receiving the approval of Dr. Goodwillie, was continued on his arrival. At 4 P.M. the temperature was 104° F.; pulse, 95. At 8 P.M., the patient was again seen by Drs. Goodwillie and Kellogg. Marked constitutional depression existed. Temperature, 102° F.; pulse, 90. Dr. Kellogg then expressed his belief, in which Dr. Goodwillie concurred, that Dr. Beard was suffering from septicæmia. The patient was again seen by Dr. Goodwillie at 10 P.M. Temperature, 102° F.; pulse, 85. Face not painful. At 9 A.M. the next morning Dr. Goodwillie cleansed the abscess. There was now no pain and little swelling of the face. The chest was examined with negative results. A consultation was then arranged for 8 P.M. Drs. J. R. Leaming, J. L. Little, and T. H. Kellogg in attendance. Temperature was found to be 102° F.; pulse, 108. Little or no swelling of the face. No cough, but some pain in the right side, referred to the region of the liver. Mind clear. By general consent Dr. Little assumed the management of the case, with Dr. J. R. Leaming in consultation. On Saturday morning Dr. Goodwillie again saw the patient, and found that the symptoms were rather more unfavorable. The

night had been passed in restlessness. Temperature, 103° F.; pulse, 105. When seen by Dr. Little on this same morning the temperature was 104° F.; pulse, 100. A cathartic was administered. On Saturday evening the temperature had fallen to 102° F. The cathartic had acted briskly.

On Sunday morning the temperature had risen to 103° F. There was dulness on the right side, bronchial breathing and crepitations. On Sunday evening Dr. Leaming saw the patient and found pleuro-pneumonia, as had previously been diagnosed by Dr. Little, and in addition he detected adhesive pleurisy of the left side (plastic exudation). Temperature, 102° F., pulse, 104-8. On Monday morning the temperature had fallen to 101° F. Dr. Leaming then stated that the affection of the right side had progressed rapidly; in the left likewise. Face flushed; pulse rapid and variable. Monday evening: Temperature, 99° F.; patient cyanotic; great difficulty in breathing. Death occurred at 10.30 A.M., Tuesday, January 23, 1883. There was no sweating throughout the attack, and the cough had been slight, though the rusty expectoration of resolving pneumonia was observed during the last twenty-four hours of life.

Post-mortem examination by Drs. T. E. Satterthwaite, and W. H. Porter: Body well nourished. Rigor mortis only slightly marked.

Thoracic cavity.—The costal cartilages contained an unusual amount of calcific material, considering the age of the deceased.

Pericardium and heart.—There was a slight excess of serum, which was clear, in the pericardial sac. Amount about one and a half ounce. The heart was found in its normal position, and neither its substance nor valves affected. The pulmonary artery contained a firm white clot, that was adherent to the wall of the vessels, and extended through the pulmonary valve into the right auricle.

Right lung.—This organ was not attached to the chest-wall at any point, but had apparently been attached recently, and then separated by the moderate pleuritic effusion that was found in the right pleural cavity. There was pneumonia of all three lobes. The lower lobe was in a condition of gray hepatization throughout; the middle lobe was solid at its outer extremity only, and was the seat of a large reddish gray, wedge-shaped infarction, the outlines of which were sharply defined by a narrow zone of vascular tissue; the upper lobe was solidified in its posterior and external portions. One inch below the right apex anteriorly there was a small nodule, which was taken to indicate the site of an old pleuritic adhesion. Along the anterior and lateral surfaces of the lower lobe, and in the interlobular fissures, there was a thick, yellowish white plastic exudation, easily detached, and evidently of recent formation. On pressure the right bronchus exuded a reddish and frothy mucus. On examining the left lung it was found to be attached to the chest anteriorly, by quite old fibrous adhesions situated in the mammillary line, and corresponding with the cartilages of the third, fourth, and fifth ribs. The apex was also attached posteriorly by old adhesions. The diaphragm was free. The lower lobe of the left lung was solid throughout.

The upper lobe was free. The secretion from the left bronchus was similar to that in the right. Along the posterior and axillary border of the lower lobe, the visceral pleura was rough, and exhibited traces of recent pleurisy. At the apex there was puckering of the lung substance, and on the anterior surface of the lobe there were depressed cicatrices. The substance of the lower lobe was deep red in color, soft, and almost pultaceous, especially near the line of the pleural exudation. It contained also in spots small areas of a grayish yellow appearance, corresponding to the distribution of the vessels, and having the appearance of small infarctions.

The *spleen* was enlarged, pale, and soft.

The *kidneys* were enlarged, soft and fatty. The capsules

were in the main non-adherent, and there was no ocular appearance of any considerable interstitial deposit.

Liver.—The right lobe was enlarged. Its substance also was extremely soft. On the surface of the right lobe there were numerous small superficial yellowish infarctions. The gall-bladder was normal in size and contents.

The *stomach* was dilated, and its mucous surface coated with a somewhat abnormal amount of mucus.

The other organs were not examined.

DR. PEABODY asked, Why is not the right lung a specimen of ordinary croupous pneumonia, clinically and pathologically?

DR. JANEWAY thought the appearance was that of ordinary gray hepatization in lobar pneumonia.

DR. SATTERTHWAITE said that so far as the lower lobe of the right lung was concerned it presented the ordinary appearance seen in the gray hepatization of lobar pneumonia; but in the upper portion of the middle lobe there was a large wedge-shaped mass, entirely different in appearance from the rest of the lobe; it was dryer than the other portions of the lung. This condition, together with the peculiar condition of the left lung, and the clinical history, he believed justified the conclusion that the case was one of embolic pneumonia.

(To be continued.)

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, February 15, 1883.

FORDYCE BARKER, M.D., LL.D., PRESIDENT, IN THE CHAIR.

DR. WILLIAM H. DRAPER read a paper on

DIET IN THE TREATMENT OF THE GOUTY DYSCRASIA.

The relations of food and normal nutrition, and the evolution of vital energy to the etiology and treatment of disease, constitutes some of the most interesting and important problems in the experience of the practical physician. It is one of the encouraging signs of the progress of scientific medicine that these problems are attracting wider and closer attention. The physician is nowadays expected to prescribe the diet as well as the drugs. It is only necessary to refer to the part which judicious feeding now plays in overcoming the consequences of malnutrition, originating either in inherited or acquired disease, to illustrate the change which has taken place in the medical mind with reference to the importance of the question of diet in its manifold relations to health and disease.

Before entering upon the immediate consideration of the subject of the paper, Dr. Draper made a few preliminary statements with regard to the accepted pathology of gout. Gout, as a disease, in the traditional acceptance of the term, is a specific arthritis characterized by the deposit of uric-acid salts in the affected articulations. Gout, as a diathesis, is an accumulation of uric-acid salts consequent upon either increased formation or defective secretion of the products of proteid metamorphosis. Recent investigations seem to indicate that the liver is chiefly concerned, not only in the metamorphosis of the carbo-hydrates, but also in the arrest and the formation of urea. Glycosuria and lithæmia in the same patient, and the frequent alternation of gouty and saccharine diabetes, are significant facts in the support of the common origin of these diseases.

The purely chemical theory of gout and its allied disorders, that it is a disease of suboxidation, has much to commend it, but it must be acknowledged that it is impossible to reduce the theory of defective oxidation to the simplicity of a chemical equation. Dr. Draper then presented some objections against this theory, such as the modification of the metabolism of the food in its chemical process by natural forces, hereditary complications, etc., and the fact that the uric-acid salts are pres-

ent in other conditions which are not necessarily accompanied by gout. Another fact worthy of notice in the consideration that excess of uric acid is an epiphenomenon in the disease and not the exciting cause, is that the power of digestion of farinaceous and saccharine foods in gout is markedly diminished. The conclusion was that the chemical pathology of this dyscrasia is still involved in considerable obscurity.

It is recognized by many that gout is a neurosis. The great variety of nervous manifestations arrest the attention in the history of the gouty person, and nervous exhaustion is well recognized as a frequent precursor of gouty disease. Again, the influence of certain diseases of the nervous centres furnish another striking analogical argument on the possibility of the nervous origin of the affection. But such considerations do not invalidate the humoral theory of the affection. The conclusion reached by the writer was that neither the chemical nor the neurotic theory is justified completely by the results of clinical experience. Whether gout is primarily a neurosis and determined by some chemical process, or whether it is primarily a chemical process and determined by some neurosis, were questions which at the present time it was impossible to answer.

The treatment of gout, based upon the theory that it is a neurosis, is chiefly successful in the acute arthropathic lesions of gouty origin. The treatment of the constitutional vice is more successfully managed upon the theory that it is due to suboxidation of foods. The treatment of the gouty dyscrasia involves primarily complete combustion of food, whether carbonaceous or nitrogenous, and has to be brought about partly by dietetic rules, partly by hygienic, and partly by medicinal treatment. The hygienic treatment embraces an abundant supply of oxygen, and the medicinal treatment the use of such drugs as facilitate oxidation, etc. The dietetic means involves the consideration of the quantity and the quality of the food best adapted to maintain health and nutrition. It is impossible to arrive at anything more than a proximate estimate with regard to the quantity of food. It is variable, and must be proportioned according to the age of the individual and his surroundings, and the amount of work he is to perform, etc. In infants the amount of food required in proportion to the weight of the body is from three to five times that required for an average ordinary working adult. In the adult regard must be constantly paid to the protection to be secured against heat and cold, and to the occupation of the individual. Excess of food may be positive or relative; that is, it may be either more than can be assimilated, or more than is required. The relation of the qualities of food in the production of the gouty diathesis may be very striking, and deserve investigation, although they are less important probably than the quantity. The farinaceous, the oleaginous, and the saccharine foods are especially indicated for the production of heat. A nitrogenous diet is best constituted to maintain the health and nutrition of persons who do not require a large amount of animal heat, and whose occupations are mental rather than physical.

Leaving the consideration of the principles which should regulate the diet, Dr. Draper remarked that the almost uniform counsel with reference to treatment of the gouty dyscrasia is, that albuminous foods should enter sparingly into the diet of gouty patients, and that the non-nitrogenous foods, especially the farinaceous, should constitute the principal aliment. His own observation had led him to the conviction that the uric-acid theory of the gouty diathesis is not supported by the results of clinical experience, and he was persuaded that restriction of diet concerning the non-nitrogenous rather than the nitrogenous foods is essential. If there is one clinical fact more obvious than another in this class of patients, it is the limited capacity they possess for assimilating the carbo-hydrates, the sugars and the starches. These substances are the most common source of

dyspeptic troubles. The clinical fact was well established that the conversion of the nitrogenous foods is rendered more complete when they contain a minimum amount of carbo-hydrates rather than by allowing the minimum amount of nitrogenous food.

The order of restriction in diet which he recommended was first with reference to sugars, especially in the state of fermentation, or ready to pass into that condition; second, farinaceous foods, and, third, fats.

Abstinence from all fermented preparations of alcohol was, perhaps, the most necessary in the order of restriction. There could be no question concerning the effects of malt liquors in the production of the gouty diathesis, especially of the stronger English and Scotch ales. The directions, therefore, with regard to fermented preparations of alcohol should be very strict. The absolute prohibition of beer should be insisted upon, and the less wine allowed the better. Sherry, madeira, and port should be especially excluded. If alcoholics were indicated, the safest preparation which could be employed was very dilute spirit taken with food, and never upon the empty stomach. Saccharine food should be restricted. The common experience of the gouty individual confirms this statement.

The amylaceous elements were the next in order to be restricted, and pure starchy foods, such as potatoes, corn, and rice, and even wheat and barley, provoke indigestion. According to his experience the fats were easily digested by most gouty dyspeptics. The value of milk in cases of persistent rebellious lithæmia was well known, and constituted a precious resource. Salads, cauliflower, cabbage, indeed almost all vegetables except those which are nearly all starch, may be used with safety. A person pursuing intellectual labor and leading an indoor life should take only a limited supply of food which requires oxidation, and had not better try puddings and the like, or endeavor to quench his thirst with beer or wine.

The paper being before the Academy, the President invited DR. A. HADDEN to open the discussion, who remarked that Dr. Draper had recommended a line of treatment very much like that which he had pursued during the last four or five years in the treatment of gouty patients. However much it might be against the practice which had obtained very many years, the clinical facts, as he had already taken occasion to state elsewhere, were well established. The use of nitrogenous food, fully allowed, had counteracted the influence of the gouty dyscrasia, and especially so in subacute and chronic cases. The urates in the blood and also in the urine had been diminished by this plan of treatment, and cutting off as far as possible the use of saccharine and starchy foods. Dr. Hadden then spoke at some length concerning observations which had been made with reference to the presence of uric-acid salts in birds in captivity, such as the parrot, pigeon, and domestic fowl, and its absence in the wild birds, such as the eagle and the vulture, etc., and also spoke of similar observations made upon domestic animals. It was quite conclusive in his mind that the line of treatment advocated would solve the perplexing problem of the gouty diathesis.

DR. PUTNAM-JACOBI remarked that the question of suboxidation was certainly most interesting, and seemed to her unquestionably true as brought forward by Dr. Draper; but simply to state that certain substances did not pass through their normal term of oxidation was not offering any explanation of the fact, certainly did not bring into any single expression the effects of heredity upon various manifestations of gout and the nervous phenomena which exist, either as a cause or as a consequence of it. She referred to the experiments of Pettenkofer and Vogt on the respiration, who had developed one fact of special interest in connection with this subject, namely, that the amount of oxygen taken up in the blood is in proportion to the amount of albumen stored up in the tissues of the animal experimented upon. It was well

known that, contrary to previous expectation, it was extremely difficult to increase the amount of oxidation by increasing the amount of oxygen. By increasing the quantity of oxygen presented to the lung the increase of oxygen which entered into the blood was very trifling; but in proportion to the increase of the albumen in the food, there is a measurable increase in the quantity of oxygen taken in, and especially that which remains stored up in the tissues. This was the result of the experiments of P. and V. Further, it was determined that the oxidation of the circulating albumen is not carried on by means of oxygen absorbed at the time, but by means of oxygen which is stored up in the tissues from previous respiration. Thus, the difference between the amount of oxidation which goes on in the day and the night is considerable; more oxygen is taken in through the day, and more oxidation goes on during the night.¹

The last terms in the long and complicated process of proteid metabolism are probably defective in gouty persons, and the extraordinary nervous manifestations, such as pertain to the heart, mental depression, etc., are especially associated with the deficient evolution of force resulting from this. It was very certain that the source of the uric acid is by no means always the result of incomplete development of urea. There is no constant relation between the excess of uric acid and deficiency in urea. It is also certain that a person in whom the gouty constitution exists may sometimes have a most profound hypochondriasis and be almost upon the verge of insanity, and yet no lithates nor quantitative excess of uric acid be found in the urine. She had had one such patient under observation, who was cured by an exclusively milk diet. She added her testimony to that of Dr. Hadden with regard to the utility of purely meat diet in irregular lithiasis, and had a great many cases which would prove it, as shown by quantitative analysis of urine giving a fall of uric acid under its use. She would like to ask Dr. Draper what he did to enable the patients to tolerate the meat diet when any difficulty was experienced in taking it.

DR. H. G. PIFFARD remarked that, some seven or eight years ago, he read a paper in which he advocated precisely the same views presented by Dr. Draper, and also referred to a paper read by Dr. Draper at about the same time, and of the same intent, namely, that gout was due in a great measure to failure of complete oxidation of the peptones, and that a hesitancy in the oxidation process led to the formation of certain acids. He thought that that view was combated by Dr. Hadden's theory and also by his facts. However, stepping aside from theories, the practical fact remained, that if we wished to be good livers we must have good livers, else we shall suffer from over-indulgence. He thought it would have been well if Dr. Draper had called attention to the fact that the effects of these various articles of diet is more apparent now than twelve or fifteen years ago, and he believed it to be due largely to the use of glucose in the manufacture of beer and wine, especially American wine. Many of the German wines, particularly Rhine wine, also contained considerable glucose.

DR. F. P. KINNICUTT corroborated the clinical experience referred to by Dr. Draper, and also spoke of the intimate relation existing between diabetes and lithæmia.

DR. JANEWAY remarked that when milk diet was spoken of as purely nitrogenous, it must be admitted that a considerable quantity of sugar was taken, and also sugar which admitted of acid fermentation.

It seemed to him, from what he had seen of gout, that the main thing should be, so far as possible, to avoid dyspeptic occurrences. This, perhaps, may be accomplished sometimes by the use of nitrogenous food, and at other times we are obliged to resort to the reverse.

Again, with regard to the pathology, if the neural

¹ It was this influence of stored albumen on the ingestion of oxygen that might probably explain why an excess of albuminous food will provide for its own oxidation and uric acid will diminish.

pathology is to be accepted, he thought we ought to see among the immense number of nervous patients gouty deposits more frequently than they are met with. According to his observation, gout was not of so frequent occurrence among nervous patients. There are other manifestations in the joints, but not gouty in character. Again, there came in the fact that gout might be determined by anæmia, and sometimes it is determined by some nervous affection, but when it did appear after some nervous phenomena, it was, perhaps, more likely due to the nervous action setting up a dyspeptic condition than acting primarily. He was inclined to accept the humoral pathology, so called, rather than the neural explanation of the affection.

THE PRESIDENT said it had seemed to him that every case of gout was a problem by itself, depending not only upon hereditary tendencies, but also upon the habits and surroundings of the patient, and also certain idiosyncrasies which make it impossible to settle upon any special plan of treatment for all. There are gouty persons in whom a single strawberry will bring on an attack; others in whom a single slice of watermelon will develop a paroxysm; still others who can eat strawberries and watermelons with the utmost freedom, and yet are unable to take the slightest quantity of roast beef. Other patients are unable to take wines or malt liquors, and at the same time may take whiskey. There are gouty patients who cannot take any alkalies without an explosion of the disease, but at the same time they are able to take strong acid wines with benefit. Several cases were related illustrating these points. The point which he wished to draw out from the author of the paper was this: It seemed to him that it was extremely difficult to lay down any system or plan of treatment or diet which will apply to all. Consequently the danger lies in our attempting to generalize and reduce any general law applicable to all cases.

DR. FLINT remarked that, concerning a comparatively nitrogenous diet, he was not prepared to offer any opinion at present. He remarked, however, that he believed we must go to clinical observations to settle many of these questions; that a sufficient number of cases treated according to this plan or that plan should be secured, from which to draw conclusions. He should feel doubtful about accepting any views concerning the pathology of the affection based either upon neurology or chemistry. He thought it desirable to collect a considerable number of cases, as nearly analogous as possible, with reference to determining, by a clinical study, which of all these forms of diet would accomplish most.

Another reflection was the consideration of the influence of heredity upon the gouty dyscrasia. Perhaps there is no disease, or but few at least, in which dyscrasia plays so strong a part as in gout. There are but few diseases in which heredity is more distinctly manifest. Then again, it is developed at a certain period of life, as a rule. Exactly in what some of these influences consisted cannot be said, but the fact should not be overlooked, and in our investigations we should make a large allowance for the existence of these elements and the differences in different persons.

DR. DRAPER, in closing the discussion, said that he had not had much difficulty in getting his patients to carry out the kind of diet recommended because he had rarely found it necessary to keep them upon a strictly and absolutely nitrogenous diet, such as Dr. Jacobi seems to have done. Occasionally he had been obliged to restrict patients absolutely from the use of sugar and to a very moderate amount of wheaten bread. He believed, however, that persons, as a rule, who were confined to a diet of this kind were very rebellious, and after a time it became necessary to grant them some indulgence. He had never found any difficulty in adding to the diet certain varieties of green succulent vegetables, and they certainly contributed a great deal to the comfort of the patient.

With regard to Dr. Janeway's remark concerning milk,

he admitted its truth. Milk contains a considerable quantity of sugar, and its administration is antagonistic to the theory that gouty patients do not digest sugar, but he believed that in the use of milk it is always necessary to give patients more or less of an alkali, and that when soda is given with the milk it is commonly very well borne.

He entirely concurred with Dr. Flint in his reflection that these questions must be settled by clinical observation, and in the review of the pathology of the affection which he gave, he endeavored to say clearly that the diet recommended could not be explained, nor justified, by either of the theories given. It was well known, and this point was worthy of special attention, that the diet which has been prescribed in gout forms a part of that which has been based upon the chemical pathology of the disease. He did not think that anybody could explain why a diet of animal food was the one which agreed with the majority of gouty persons. And yet he believed that from his own experience it was absolutely true that it did agree with them, and that it was the best means of protecting these patients against the subjective and objective symptoms of the disease.

With regard to Dr. Barker's observation, he presumed that the experience of every physician could furnish a great variety of apparently contradictory facts, such as he had mentioned. So far as he was concerned, he was unable to explain them. Why an attack is determined by a single strawberry or a single slice of water-melon, or indulgence in grapes, he was unable to explain, unless it was upon the basis of the neural pathology, and that there was something in the nervous system of the person having the gouty dyscrasia which rendered him particularly susceptible to the irritations which are conveyed in certain articles of diet. Dr. Janeway had stated that he believed the majority of nervous patients, women for example, are very seldom gouty. Dr. Draper admitted that a great many of them were not, but he was quite sure that a great many of them were, although they have not had arthritic lesions, and he thought we were often led to wrong conclusions in supposing that gout did not exist on account of the absence of the arthritic affection. Other manifestations of this dyscrasia may be present, such as the dyspepsia provoked by fermented liquors, or the cutaneous irritations, or the inflammatory manifestations, or the hypochondriasis, and hysterical disturbance so common among men and women in the later periods of adult life.

DR. HADDEN stated that in his cases milk was not well borne, and he thought the fact was explained probably by the presence of the sugar in the milk. As a substitute for the gluten bread he had used wheaten bread thoroughly toasted.

The Academy then adjourned.

THE LICENCE-TAX ON PHYSICIANS IN VIRGINIA.—At the last session of the Virginia Legislature, the State licence-tax on physicians residing in cities and towns of 5,000 inhabitants or upward, was raised from fifteen to twenty-five dollars; and throughout the State the discrimination was made between city and country doctors to the extent of making city physicians pay *ten dollars* more than the country physician for the same thing. The *Southern Clinic* protests strongly both against the discrimination and the tax. The State, we are told, makes no provision for her sick poor, but expects the doctors to look after them gratis.

AN ALLEGED CASE OF LEPROSY IN DELAWARE.—Some excitement was caused at Lewes, Del., recently, by the landing of a stranger from an English vessel, who confessed to being a victim of leprosy. The man was of English birth, but had contracted the disease in Madagascar about ten years before.

Correspondence.

SECONDARY PUERPERAL HEMORRHAGE
COMPLICATING SEPTIC ENDOMETRITIS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: The interest awakened in the subject of secondary puerperal hemorrhage by the reading of a paper with that title, at the Academy of Medicine, on January 18th, by Dr. Paul F. Mundé, prompts me to publish the following somewhat detailed history of a case, in a number of respects like the one reported in that paper.

The patient was Mary C—, a native of Ireland, aged twenty-one. She was a primipara, and was seen by me two weeks previous to her confinement.

Previous history.—Although never robust, the patient had enjoyed fairly good health up to one year prior to the present pregnancy, at which time she contracted an initial lesion, which was followed by prolonged secondary manifestations. When I saw her, all that indicated the constitutional disease was a profound condition of anæmia.

Parturient history.—She was taken in labor at 10 A.M. on Wednesday; I saw her three hours later. On examination per vaginam I found a roomy vagina and pelvis of normal dimensions. The cervix was high up, soft, and distensible, and through the os, which was dilated to the diameter of a silver quarter of a dollar, the intact membranes were protruding. Passing the finger through the os, I made out the vertex presenting with the occiput to the right and anteriorly. Further examination proved that the head was hydrocephalic and somewhat enlarged. The fetal heat was 152°. The pains were slight, but together with her excitement, enough to keep her awake and uncomfortable. I therefore had administered chloral hydrate, 15 gr. per rectum, under the influence of which she soon fell asleep and slumbered until the membranes ruptured, which occurred about one hour before the os was fully dilated. The first stage lasted ten hours.

Seven hours later the head had descended to the inferior strait, but ceased to advance. After waiting half an hour, I had chloroform administered, and delivered with the forceps a living hydrocephalic male child. The second stage was of eight hours' duration.

After gentle massage at the fundus uteri there were delivered in eight minutes the placenta and membranes intact. Five minutes later the woman had come up from under the influence of the anæsthetic enough to be able to swallow one drachm of Squibb's fluid extract of ergot, which I invariably administer after the delivery of the placenta. A second drachm dose was given as soon as she was perfectly restored to consciousness. I held my hand at the fundus uteri for one hour after delivery, being occasionally relieved by the nurse, and when I left the patient's bedside the uterus was firmly contracted, the pulse was 100, and she had fallen into a quiet sleep. The cervix and perineum were uninjured.

Puerperal history.—During the following eleven days her average temperature was over 100° F., the highest thermometric point reached being 103° F.; this occurred on the third day, and followed a well-marked rigor. During all this period her pulse was over 100 and very small. The uterus underwent involution somewhat slowly, and was slightly tender when moderately compressed between the hands during conjoined manipulation. The os was widely gaping, and the finger through it felt the lining membrane of the uterus soft and boggy.

The lochia were suppressed for twenty-four hours after the chill, and when they returned were scanty at first, but later became very profuse, and varied from time to time from a grumous to a serous fluid. The odor was at all times offensive, and occasionally markedly foul.

I diagnosed the condition as being puerperal septic endometritis. The treatment consisted of intra-uterine and vaginal injections of hot dilute solutions of carbolic acid.

On the twelfth day the temperature went up to 102½° F., while the pulse ranged from 120 to 130. I attributed the rise of temperature to the separation of the slough at the placental site, by which a solution of continuity was caused, and this, by opening up mouths capable of drinking in from the septic matters present in abundance in the cavity of the uterus, allowed of a sudden although slight general septic intoxication.

After washing out the uterus the temperature steadily fell, until at 8 A.M. of the following day it was normal, and she was feeling better than at any time since her delivery. This was the morning of the thirteenth day; about 10 A.M. I was summoned to her by the message that she was dangerously flooding. I arrived twenty minutes after the bleeding began, and found her extremely exsanguinated. The bed, bedding, and clothing were saturated with blood, while a large mass of clots lay in the bed between her thighs. The vagina contained a number of soft clots; these I gently removed, and was much relieved to discover that the bleeding had ceased. The pulse ranged from 150 to 160, the lips were absolutely without color, and the countenance was blanched and anxious. The patient's intellect was clouded and she had slight hallucinations. The uterus had not been distended by the blood, as it was not perceptibly increased in size, so far as I could make out by gentle abdominal palpation. I gave her hypodermically ten grains of ergotine, and had her partake freely of alcoholic stimulants and iced milk. She was allowed to lie upon the bloody sheets, and nothing was in any way disturbed about her. The bleeding recurred again twice or three times during the day, but the amounts of blood lost were so trifling that I was not sent for. Twelve hours after the bleeding occurred, I had dry linen placed under her, and after having a second hypodermic of ergotine, she was left undisturbed for the night.

For eighteen days after the hemorrhage the temperature remained above normal, and it was over six weeks before her general health began to show marked signs of improvement. Her uterus remained in a state of subinvolution. I would say in conclusion:

First.—I believe that puerperal septic endometritis occurs separate and distinct from metritis more frequently than is generally supposed. The slight symptoms it gives rise to are usually attributed to light general septic poisoning.

Second.—The above condition may undoubtedly cause secondary puerperal hemorrhage. This is probably brought on by the separation of an unhealthy slough from abnormal tissue at the placental implantation, and this, by opening up the mouths of the uterine sinuses, allows of free, or it may be even fatal bleeding.

T. T. GAUNT, M.D.

132 WEST TWENTY-THIRD STREET, NEW YORK.

Army News.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from February 10, 1883, to February 17, 1883.

BROWN, JOS. B., Lieutenant-Colonel and Surgeon. Detailed as member of Board for Examination of Assistant-Surgeons for Promotion, and Candidates for Admission into the Medical Corps, United States Army, to convene at New York City on March 1, 1883. S. O. 35, par. 1, A. G. O., February 10, 1883.

CLEMENS, BENNETT A., Major and Surgeon. Detailed as member of Board for Examination of Assistant-Surgeons for Promotion and Candidates for Admission into the Medical Corps, United States Army, to convene at New York City on March 1, 1883. S. O. 35, par. 1, A. G. O., February 10, 1883.

JANEWAY, JOHN H., Major and Surgeon. Detailed as

member of Board for Examination of Assistant-Surgeons for Promotion and Candidates for Admission into the Medical Corps, United States Army, to convene at New York City on March 1, 1883. S. O. 35, par. 1, A. G. O., February 10, 1883.

TOWN, FRANCIS L., Major and Surgeon. Is relieved from duty at Fort Walla Walla, and will report to Commanding Officer, Vancouver Barracks, for duty as Post Surgeon. S. O. 7, Department of the Columbia, January 27, 1883.

WOODWARD, J. J., Major and Surgeon. The extension of leave of absence, on account of sickness, granted October 6, 1882, is further extended six months, on account of sickness. S. O. 34, par. 9, A. G. O., February 9, 1883.

DE LOFFRE, AUGUSTUS A., Captain and Assistant-Surgeon. Relieved from further duty in this Department. S. O. 28, Department of the Missouri, February 5, 1883.

NEWTON, R. C., First Lieutenant and Assistant-Surgeon. Is relieved from duty at Fort Cummings, N. M., and will proceed to Fort Sill, I. T., and report to the Commanding Officer for duty. S. O. 28, Department of the Missouri, February 5, 1883.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Comparative statement of cases of contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending February 17, 1883:

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
February 10, 1883.....	0	4	69	6	73	41	0	0
February 17, 1883	0	2	85	7	75	51	0	0

THE TARIFF ON SKELETONS.—In the present agitation over the questions of tariff and free trade, the needs of our Western anatomists should not be forgotten. The Chicago correspondent of *The British Trade Journal*, in enumerating the principal articles of import into that city, such as human hair, wigs, lace, nets, etc., says:

"Curiously enough, foreign skeletons of the genus *homo* are largely imported into Chicago, and are sold at less cost than they can be scraped, dressed, and mounted here. This, notwithstanding that we have no lack of pauper subjects, buried at the expense of the county of Cook, and on which our medical colleges largely depend for their cadavers. Still, will it be believed, these foreign skeletons are loaded down by a tariff of thirty-five per cent? This, too, is in face of the fact that the laws against 'resurrectionists' are extremely stringent in this and other Western States."

YOUNG AMERICA.—At the close of Dr. Morell Mackenzie's lecture at the Bellevue Medical College, New York, one of the students from "out West" remarked to his neighbor, "That feller talks our language very well for a foreigner."—*Lancet*.

THE MASSACHUSETTS GENERAL HOSPITAL.—Governor Butler has nominated Dr. Henry G. Clark as a State trustee of the Massachusetts General Hospital, in place of Mr. William Endicott, Jr. This hospital is to begin in March the erection of a large addition to the present quarters of the Out-patient Department. There were treated last year in this department over sixteen thou-

sand five hundred patients; and the present accommodations are too limited. There are male and female medical, surgical, nervous, eye, throat, and skin departments, as well as the dental clinic of the Dental School.

The new Thayer building for nurses is to be open by April 1st. This is a substantial brick structure, and will accommodate fifty-four nurses, giving each a separate room; and it contains a large parlor, and suite of rooms for the Superintendent of the Training School.

A most successful department of the hospital is the Convalescent Home at Waverly, beautifully situated on high land, convenient to the railroad station, and but a few miles from the city. It has now been open ten months, and has fulfilled everything hoped for by its projectors. The average number of patients has been ten. The medical officer in immediate charge is one of the surgical externes of the hospital. Those cases, so familiar to every hospital surgeon, that after operation advance to a certain point, and then remain stationary or begin to sink, are here found to recover rapidly, and many lives are saved that would be lost in the air of a city hospital.

THE MEDICAL LIBRARY ASSOCIATION, of Boston, has added to its library a new circulating department, which is intended to furnish the latest works to members at a low rate per day.

SMALL-POX IN BOSTON.—One case of small-pox recently arrived in Boston from Baltimore, by steamer. The Board of Health ordered vessels from that port to be quarantined accordingly.

AN UNPLEASANT AURAL INTRUDER.—Apropos of the late discussion in *THE MEDICAL RECORD*, on the Removal of Foreign Bodies from the Ear, Dr. J. M. W. Kitchen offers the following bit of experience: "On the 9th inst., during my service at the Metropolitan Throat Hospital, a German woman appeared and complained of trouble in her ear. She said that at twelve o'clock at night (eighteen hours previous), she had experienced 'a crawling in her cheek, and now she had it in her ear and knew it was there.' This was somewhat indefinite, but inspection showed that a brown shining body, resembling dried cerumen, covered the drum-head. Cautious touch with a probe disclosed the fact that the body was alive, and that the patient felt 'him scratching her head out.' Considering the insect's formidable claws, it must have created an unpleasant sensation, to say the least, to have it clawing at the sensitive membrane. The insect filled up the lumen of the canal completely, and was in close contact with the drum-head. The patient had prodded it in with a hair-pin. It could not turn around, and it could or would not back out; but it squirmed and twisted away from forceps and hooks in a marvellous manner, its horny shell being very slippery. It at last became evident that the bug must die, and finally, oil not being at hand, I succeeded in piercing its abdomen with Dr. Wagner's sharp-pointed cotton holder, and then poured a weak solution of carbolic acid into the canal. This procedure reduced the creature's vitality to the desired point; and then an improvised square flat hook being pressed between the insect and the wall of the canal, and a quarter turn being made, the hook engaged with some part of his anatomy, and he was dragged ignominiously into the outer world, much to the patient's relief, and putting an end to the discussion that was arising in my mind as to whether I should call with the patient upon Dr. Sexton or Dr. Knapp, for the help that their several instrumental aural armaments might afford. The insect looked like a young cockroach, and was one-half inch in length."

WHAT THE DOCTOR IS EXPECTED TO DO FOR NOTHING.—A correspondent from Pennsylvania writes: "In your issue of January 20, 1883, you compare the fees paid the medical attendants of the late President and those of the lawyers in the Star Route cases, also call at-

tention to the pay of surgeons on ocean steamers. Bearing on the same subject, is it not time for the profession to consider how generally their services are underrated, or rather, how much more gratuitous service is expected from them than any other class? Is a hospital established, other expenses may be liberally met, but physicians must be satisfied with honor alone, in return for a liberal daily expenditure of time and the best skill the city affords, and the resident physicians must give all time and not leave the premises without permission, and yet *pay their board in advance*; at least this was the custom in the City (Blockley) Hospital in Philadelphia, twenty years ago, and I suppose is now. This general idea applies to all the dealings of the public with the profession. No matter how liberally other expenses are compensated, physicians must serve the public for honor. Can you mention any other profession, trade, or business where liberal pay is not expected for all services? Apprentices, clerks, lawyers, students, get paid for their services while learning the business, and criminals who claim to be unable to employ counsel, either have a lawyer furnished by the State or go without. My personal experience bears this out, living here among the miners. Let one be injured, liberal collections are often made to pay his grocer, etc., but never a cent for the doctor; on the contrary, he is generally expected, while giving constant daily attention, perhaps for months, to contribute more than his fair proportion for other expenses. Several years ago a wealthy corporation called upon me to attend one of their men, who was terribly injured by an explosion. It required constant attention for several months, at a distance of six miles from my home. They paid the patient's board, furnished him a nurse and all other necessary expenses, but when the man finally got well, told me that they were incorporated to mine coal, not pay doctors. All are under the universal idea that the profession is under special obligation to work for the poor gratuitously. Where else will not the same amount of skill and education command better remuneration than in the medical profession, when public services are to be performed, and where else is the same amount of gratuitous services required?"

AN ANTI-QUACK WRAPPER.—Dr. F. H. Darby, of Morrow, Ohio, has published a four-paged and double-columned sheet wrapper, filled with useful information for the sick; designed for druggists and physicians who dispense their own medicine. It can be torn into halves, quarters, eighths or sixteenths, without marring the printed matter. The paragraphs comprise abbreviations of that portion of the Code of Ethics relating to "The duties of patients to their Physicians," useful receipts, etc. Dr. Darby says that these wrappers can be supplied at a very nominal cost.

DISSOLVING COAGULA IN THE BLADDER.—Dr. W. Titus, of Newark, N. J., reports a case of hemorrhage into the bladder in which the resulting clots were satisfactorily dissolved by the injection of a solution of pepsin.

HYSTERICAL HAIR-CURLING.—A very curious and unique case, which is denominated as above by Mr. Le Page, of Durham, England, hysterical hair-curling, is reported in the *Lancet*. The history is suspicious, but the facts are well vouched for, as will be seen. The patient, aged seventeen, with a history of irregular menstruation, had felt ill with various neurotic symptoms, and a feeling of "pins and needles" over the scalp and general numbness of sensation. In the evening she washed her head in tepid water. After partially drying her hair with a towel (she did not approach a small fire which was in the room), and while so engaged in the presence of her parents, nearly the whole of the hair on the right side of her head drew up into a hard lump, and felt as if it would pull the roots out. Her father and mother were engaged until nearly two o'clock the next morning in the endeavor to untangle and straighten the almost solid mass, with but little

success. The few ends combed out were spread on a pillow she then slept on; on awaking they found them drawn up as before. The hair on the left side of the head was quite smooth, very lightly waved, and not in the least tangled or drawn up. Viewed with the microscope, it was evident all the hairs which are contracted are flat, while those hairs which remain comparatively straight or looped and festooned are round. This disposed of a shadow of suspicion which naturally accompanies any unexplained phenomenon in a "hysterical" female. Viewed without the microscope, it was at once evident that no dexterity could have produced the condition of the hair. Mr. Le Page's hypothesis in explanation of the case is that excessive nerve-tension found vent in the pigmentary portion of the hair—viz., that some change analogous to electrolysis took place in the medullary portion, leading to chemical change, decrease of bulk, and contraction. Sir Erasmus Wilson regarded the condition as very interesting and extraordinary, and, as never seen by himself, had desired and received permission to deposit Mr. Le Page's specimen in the dermatological department of the museum of the Royal College of Surgeons of England.

THE REMOVAL OF A FOREIGN BODY FROM THE EXTERNAL MEATUS.—Dr. E. L. Holmes, of Chicago, writes: "The perusal of quite recent articles on this subject in *THE RECORD* leads me to relate an experience in removing, some years since, a pebble firmly impacted in the external meatus of a boy six years of age.

"Inspection showed that no form of forceps could grasp the stone, as it had been pressed with considerable force deep into the external meatus, in malicious sport, by an older companion.

"A protracted use of the syringe failed to dislodge the foreign body.

"As I had but one ordinary steel hook, it occurred to me to employ with it an old and unusually large cystiotome used in cataract operations.

"After the administration of ether, the hook and then the cystiotome were each in turn pressed between the stone and walls of the meatus, with little injury of the integument. The handles of the instruments, parallel and near each other, were then so turned that the points of the hooks were directed to the axis of the meatus. The instruments, held firmly together, were withdrawn with considerable difficulty, bringing with them the stone.

"A special instrument with two hooks could be constructed, with suitable handles and a simple 'lock.' Properly introduced and 'locked,' they would constitute in fact a double hook.

"I have never met, in a long experience, with another case in which a hard foreign body in the ear was not removed by syringing.

"A very hard substance, equal in size to the diameter of the meatus, and crowded against the membrana tympani presents to the aurist a serious problem. Such a contingency is rare, and does not fall within the purpose of this communication."

ON THE MEANING OF THE WORDS NYCTALOPIA AND HEMERALOPIA.—Mr. Tweedy communicates to the "Royal London Ophthalmic Hospital Reports" a long and learned article, discussing, in all its bearings, this much-vexed question, and arrives at the conclusion, now generally accepted, that the true meaning of nyctalopia is night-blindness (*ὁ τῆς νυκτὸς ἀλαός*), and, consequently, that the true meaning of hemeralopia is day-blindness.

GOATS AND HOMŒOPATHY.—It is a pleasure to learn that the goat is an animal which responds well to homœopathic remedies. In Surrey, England, there is a goat farm where *Guillemus capricornis* is raised and milked for the alleged benefit of the babies of London. A visitor says: "The goats, young and old, appear clean and perfectly healthy; their bright, hairy coats are subjected to curry-combing; no troublesome foot disease

demands attention as in the case of sheep, and any internal ailments are promptly and successfully dealt with by homœopathic medicines, of which the manager, Mr. Farrer, speaks with the greatest confidence and satisfaction." We should like very much to have Mr. F. report to us some cases. No doubt infinitesimal doses will affect a credulous man, but not a sensible goat.—*Journal of Comparative Medicine*.

DONATION TO VETERINARY COLLEGE.—A subscription of \$10,000 from Mr. J. B. Lippincott, for the establishment of a veterinary college in connection with the University of Pennsylvania, was received by the trustees of that institution, recently.

THE ACTION OF PILOCARPIN UPON HORSES.—After a subcutaneous injection of pilocarpin (gr. j.) the saliva begins to flow and continues for about an hour. The injection of a large dose (gr. iij.) will cause the secretion of one or two quarts of saliva in a short time. There is also a considerable discharge from the conjunctival and nasal mucous membranes. The temperature rises from two-fifths to one degree F. The heart beats faster by five to ten pulsations. General perspiration does not often occur. Frequent urination will be noticed. After several days' use of pilocarpin the feces become softer. The horse does not seem to be weakened or made less active by the drug. It has been found somewhat useful in diminishing dropsy from kidney or heart disease, also in lessening the amount of pleuræ effusion (in dogs). Its action on the heart is weakening—a fact to be remembered.—*Journal of Comparative Medicine*.

THE REIGN OF ABSINTHE IS DRAWING TO A CLOSE.—A rival has invaded its dominions and is making most rapid progress. The new beverage is called Amer-Picon—that is, Picon Bitters. It is said to be tonic, to assist digestion, to be an aperient and a febrifuge, and withal an agreeable stimulant. The Amer-Picon is prepared from Algerian plants, and it is more than thirty years since M. Gaetan Picon began to make it in that colony.

THE STIMULATING PROPERTIES OF OATS.—We have heard much lately about the remarkable therapeutical powers of *avena sativa*, which powers have been generally discredited. M. Bouley recently presented to the Académie des Sciences the results of investigations by M. A. Sansom upon the subject. Experiments were carried on at the Ecole de Grignon. With the aid of Du Bois Reymond's apparatus, the neuro-muscular excitability in horses was tested before and after the ingestion of oats. Numerous and repeated experiments have established, says M. Sansom, the following facts:

1. The pericarp of the oat contains a substance, soluble in alcohol, which has the property of stimulating the motor cells of the nervous system.

2. This substance is nitrogenous, and probably belongs to the group of the alkaloids. It is uncrystallizable, brownish, finely granular. Its formula (subject to verification) is $C_{10}H_{21}NO_{15}$. It is called *avenine*.

3. All varieties of oats contain some of this alkaloid, but not to an equal extent. The differences depend upon soil as well as variety. The *variété noire* generally contains the most.

4. If the amount of avenine is below 0.9 per cent. of dried oats, it is insufficient to cause excitation.

No facts are given regarding the effect of the avenine upon the human organism.

UNION BY FIRST INTENTION IN SCALP WOUNDS.—Dr. Robert T. Morris, of Bellevue Hospital, N. Y., gives the following directions for securing primary union in scalp wounds:

Let us take for example a typical case.

A man in good health is struck upon the head by a falling beam, and receives a lacerated and moderately contused wound. The wound is a couple of inches long,

extending entirely through the skin, and gaping perhaps to the extent of a quarter of an inch. The bleeding is so profuse that the patient comes to you promptly, thereby giving you a great advantage.

Of course the first thing to be done is to make sufficient pressure to control the hemorrhage, and then the hair is carefully trimmed away from the edges and vicinity of the wound. A patient who is bald here finds for the first time a redeeming feature to his condition.

After sufficient hair has been removed a thorough syringing of the wound with carbolyzed water (1-30) should follow, and then a most thorough search must be made for any foreign body, a single hair left in the cut being sufficient to prevent union by first intention in its vicinity.

Twist together two or three horse hairs which have been kept in carbolyzed oil and lay them in the wound, allowing the ends to project from either extremity, and then, with a medium-sized curved needle, put in enough silk sutures to bring the edges of the skin closely in apposition, taking care that the needle penetrates the entire thickness of the skin each time that it is inserted.

After all of the sutures have been tied, the horse-hairs should be pulled back and forth a little by means of their projecting ends, in order that the canal for deep drainage may be free.

Superficial drainage is next to be looked after, and this end may be gained very nicely by wringing out six or seven thicknesses of cheese cloth in carbolyzed water (1-30), and applying as a compress on the wound, first rubbing a little iodoform well into the portion which is to come next the skin. Gutta-percha tissue, or any other waterproof material, should then be placed over the cheese cloth, and the edges allowed to project far enough over so that everything beneath will remain moist and warm. A bandage applied not too tightly completes the dressing.

In twenty-four hours the horse hair may be removed, and the dressings replaced. In forty-eight hours or later, the stitches should be removed, and a warm and dry dressing placed over the site of the wound. If the patient is asked to return for examination in a day or two, the wound will almost always be found to have united beautifully by first intention, and a long period of suppuration, with numerous complications, to have been avoided.

When failure occurs in a case like the one described, the causes are usually due to lack of care in the application of the deep or superficial drainage.

The sutures may have been tied more tightly than necessary, or some foreign material may have been left in the wound.

HEART SCANNING, OR THE METRICAL TREATMENT OF THE PULSE.—Dr. Samuel W. Francis, of Newport, R. I., says that the normal "beat" of a healthy heart is iambic, — ; and that when it is trochaic —, pyrrhic —, or like a spondee —, it should be regarded as a signal, to the physician, that there is something wrong, which calls for a thorough investigation by auscultation and percussion.

Dr. Francis also reports a case where the pulse was only 29 to the minute; and the beat dactylic — —: the long and two short being well marked. The patient was a lady, sixty years of age, who recovered under diffusible stimulants and counter-irritation.

INEBRIETY AND THE TEETH.—The pastor of a large mission chapel in this city is in the habit of using moral compulsion with his people to have them keep their teeth in good condition. If any one has bad teeth he is sent to a dentist, who fills or extracts them, as may be needed. A dentist is supplied who does the work for nothing, if the patient cannot afford to pay. The clergyman in question states that he has had much less trouble from drunkenness since he adopted this plan. We commend it to the attention of our inebriate specialists.

COURSE), RUSH MEDICAL COLLEGE, CHICAGO.

LECTURE II.

SEPSIS AND ANTISEPTIC SURGERY.

THE infectious diseases usually consequent upon wounds, and therefore falling within the province of the surgeon, merit somewhat extended discussion. Such diseases were known to the earliest medical writers, and, we may assume, antedate man himself by so much time as the existence of highly organized life preceded him. Clinical experience had, long before the advent of experimental research, identified infectious septic material with the products of that complicated process whereby lifeless organic substances are de- and re-composed into chemically less complex matters—putrefaction; and early experimental investigation was directed to the elucidation of that process and its relations to disease. Gaspard first proved experimentally that the injection of putrefying substances of animal or vegetable origin—blood, pus, bile—was followed by the clinical features of sepsis. Panum demonstrated that the putrid infectious substance is not gaseous; that it is not destroyed by eleven hours' boiling and complete desiccation; that it is insoluble in alcohol, but present in the watery extract of putrid materials, even when dried; that the albuminous matters in putrid fluids are not *per se* septic, but condense the infectious matter upon their surfaces; for the filtrate, containing no solid particles, preserves the septic properties unimpaired. Panum concluded that the putrid agent must be a definite chemical compound like curare and the alkaloids, and named this hypothetical substance sepsin. Billroth, Weber, Hemmer, and Schweninger repeated and confirmed these experiments. The last-named observer concluded from the fact that different results followed the administration of the same quantity of the same putrid liquid at different stages of putrefaction, that not one only, but various putrid products, arising at different periods of the process, possess septic properties. Bergmann and Schmiedeberg obtained from putrefying beer-yeast a crystalline substance, melting on contact with air and charring under heat, which induced in dogs the clinical and anatomical appearances of sepsis. This they termed sulphate of sepsin. Zuelzer and Sonnenschein isolated a similar compound. Hiller and Mikulicz demonstrated that the septic agent of putrid materials could be extracted and retained by glycerine, and in so far was analogous to the active ingredient of vaccine lymph, to pepsin, ptyalin, etc.

It was thus established, and so remains, that the clinical and anatomical features of septicæmia could be induced by unorganized substances obtained from the products of putrefaction. Yet in these cases two char-

acteristics, frequently observed in the septic infection of human subjects were often conspicuously absent—the stage of incubation and the infectiousness of the septic blood and tissues. Panum noted particularly that the influence of his boiled putrid materials became manifest in fifteen minutes to two hours, and attained its acme in four to eight hours. Meanwhile a new path of investigation had been opened by Pasteur's demonstration that the putrefaction of animal tissues is a phenomenon incident to the vital activity of certain bacteria—facts established incontestably by the researches of Pasteur, Tyndall, Traube, Brefeld, and their pupils. The determination of the relation between the bacteria and the diseases caused by the putrid products of their vital action soon became the object of most patient and careful investigation. Coze and Feltz found vibrios *intra vitam* in the blood of animals infected with putrid fluids; and similar organisms post-mortem in the blood of a patient dead of putrid infection. With this blood they inoculated a rabbit, which then exhibited septic symptoms, and whose blood was found to contain similar vibrios. Rindfleisch found colonies of bacteria in the heart-muscle from a case of pyæmia; Recklinghausen and Waldeyer followed with similar discoveries. The work of Klebs on "Gunshot Wounds" (1872) opened the new epoch in pathological investigation. The examination of numerous gunshot wounds, both before and after death, showed that the organs and tissues exhibiting morbid changes due to such wounds were populated by bacteria; serous surfaces, both those opened by the bullet and those which, though still intact, lay adjacent to an abscess or to the track of the missile; the walls of blood-vessels, not only those which had been the seat of secondary hemorrhage, but also those which, while not ruptured, showed beginning thrombus formation; metastatic abscesses in liver and lung; leucocytes in and near the track of the bullet—all contained colonies of bacteria. A series of experiments upon animals showed that while the injection of putrid liquids, containing naturally myriads of bacteria, was followed by continuous fever and metastatic abscesses—*i.e.*, pyæmia—the injection of the same liquids after filtering through clay and thus deprived of solid particles, including the organisms, was followed by fever just as intense, though transient, but never by metastatic abscesses—*i.e.*, septicæmia.

The work of Klebs, which proved that there must be some intimate relation between the pathological processes and the bacteria, was soon followed by a series of accurate experimental observations by Samuel, from which he concluded that the varying effects of putrid fluids upon the living animal were due to various substances therein contained; that the specific septic (toxic) influence is the effect of certain volatile matters, probably combinations of sulphur and of ammonia; to the bacteria he ascribed the influence whereby the infection is localized progressively in various organs remote from the original wound.

Billroth concluded, as the result of much careful clinical and experimental observation, that the presence of bacteria was the result and not the cause of certain changes in secretions and tissues. He assumed the formation, during inflammation and putrefaction, of a "zymoid" substance whose presence (1) conferred upon pus and exudate their infectious character and (2) converted wound secretions into favorable soil for organisms. He believed, however, that bacteria might be the

means for transporting and multiplying his hypothetical zymoid, and in this capacity might be, probably are, the carriers and originators of specific pathological processes. Since the publication of this work (1874), Billroth has materially modified certain of his conclusions.

From these investigations it was generally concluded that septic infection was due to an unorganized though perhaps organic substance; that the presence of bacteria was an epiphenomenon—a sequence, not a cause; that their deleterious agency, if any, consisted simply in the transfer of unorganized infectious matters from one part of the body to other portions, perhaps from one individual to another.

But there soon appeared from various sources, notably Koch and Pasteur, investigations more or less incompatible with these views. Pasteur found that in the serous sacs, muscles, liver, and spleen of a septicallly infected animal there are always present microscopic organisms (*microbe septique*), although the blood may be until death free from them. Inoculation with a drop of peritoneal serum, or a piece of muscle from an animal dead of sepsis, induces, in a second animal, all the appearances, ante- and post-mortem, of the original disease; while a drop of blood from the heart-cavity (proven microscopically to contain no septic vibrios) is, on the contrary, innocuous. Pasteur cultivated his vibrio septique in various fluids, such as solution of beef extract, in the manner already described; and found that a drop of fluid from the last flask, containing presumably none of the original unorganized septic matters, but crowded with the vibrios, produced the original septic disease. In the tissues of infected animals Pasteur was unable to find any unorganized substance capable of inducing sepsis, as had been affirmed by Panum, but he found that a putrid fluid, a few drops of which induced sepsis and death, lost its poisonous properties entirely in a few hours, when exposed in a thin layer to the air. Now, since the vibrios likewise lose their vitality in a few hours in the presence of free oxygen, Pasteur insists that the loss of virulence in the fluid is due solely to the enforced inactivity of the contained vibrios. Yet he is inclined to the belief that just as the alcoholic fermentation of grape sugar is a vital phenomenon manifested by any one of several species of fungi, so the production of septic substances may accompany the vital activity of any one of several different bacteria.

Pasteur further reports that among the organisms usually present in ordinary water is one identical morphologically with the bacteria termo, but physiologically distinguished by the fact that its injection from an isolated cultivation under the skin of a rabbit is followed by abscess formation at the site of puncture. Injection of the same organisms directly into the circulation, or in several places subcutaneously, is followed by the formation of abscesses in lungs and liver; by fever and death—in short, by pyæmia. A piece of the liver or lung develops in a culture liquid, the same micrococcus in great numbers. Such liquid, if previously boiled, however, so as to destroy the organisms therein contained, causes, upon subcutaneous injection, abscesses as before, but without general infection of the animal. He rejects, therefore, for pyæmia as for septicæmia, the agency of an unorganized, soluble septic agent, and considers the bacteria alone responsible for septic infection.

Markedly different was the reception accorded to a monograph published in 1878, by a then almost unknown young German physician, Robert Koch. He surmounted, by improvements in technique, some of the hitherto insuperable difficulties in the recognition and investigation of bacteria—improvements which confer such evident and extreme advantages that they have become absolute necessities for original research in this field; indeed so many errors of commission, as well as of omission, have been thereby detected in other methods, that one is disposed to regard as uncertain any researches in which these measures most essential to accuracy of observation

are neglected. Having demonstrated the life history of the bacillus anthracis, which the French school, working with Pasteur's clumsy method, had for sixteen years failed to discover, Koch turned his attention to the etiology of surgical infectious diseases. He found that the subcutaneous injection into a mouse of five drops of putrid blood was followed by immediate prostration, and in four to eight hours by the death of the animal. There occurred in these cases no local reaction, the internal organs were apparently normal, no bacteria were detected in the blood or tissues, inoculation of other animals with the blood from the heart caused no perceptible effect. Koch considers this disease, therefore, as septicæmia, etymologically as well as clinically—the introduction into the blood of a poisonous substance, soluble, not reproducing itself, analogous, in fact, with the effect of certain vegetable alkaloids and of ptomain, the substance isolated by Selmi from human corpses, which so closely resembles atropine in its physiological effects. This is also the effect obtained from the injection of boiled putrid materials by Panum, Bergmann, and Schmiedeberg, and others. Koch found, however, that the injection of a smaller quantity, one-half to one drop of the same putrid blood, was followed by entirely different effects. In some cases the mouse was apparently unaffected; in others brief, transient depression was observed; in perhaps one-third of the cases there ensued, twenty-four hours later, progressive weakness, retardation of respiration, drowsiness, and, in forty to sixty hours, death. Section revealed no other pathological changes than local œdema at site of inoculation and decided enlargement of the spleen; but after inoculation of a second mouse with a minute quantity (one-tenth to one-half drop) of liquid from this œdema, or of blood from the heart, the latter animal presented, in forty to sixty hours, precisely the same clinical and pathological picture as the first; from the second, a third was successfully inoculated, and so on *ad libitum*; indeed, the mere contact with a fresh wound of a scalpel-point previously dipped in the septic blood sufficed. Here, then, was something entirely different from the intoxication following injection of a larger quantity (five to ten drops)—differing in the existence of a marked stage of incubation, of local reaction, and in certain and uniform infectiousness. The blood of such an animal evidently contained something not present in that of the former mouse—a something requiring time for the manifestation of its influence, and finally distributing itself throughout the entire blood-mass, so that each drop thereof possessed the septic possibilities of the original, putrid drop. Such mode of action implies reproduction, and reproduction is a characteristic of organized matter. It was to be expected *à priori*, therefore, that the blood contained organisms; Koch found, in fact, invariably, that the blood serum, white blood-corpuscles, and various tissues of such animals swarmed with minute rods, which stained readily with aniline colors, and when removed from the body into similar artificial conditions multiplied by transverse fission. Since the blood of the infected and infecting mouse differs evidently from that of the intoxicated and non-infecting mouse only in the presence of these bacteria, Koch ascribes the infectiousness to these organisms. It is interesting to note that all attempts to inoculate rabbits and field-mice with the septic blood were fruitless. The animals remained unaffected; no bacilli were found in their blood, although the mouse-blood used for inoculation was full of them. Further, that although the putrid fluids injected contained organisms of numerous varieties—micrococci, bacteria, bacilli—all of which were subsequently found in the local œdematous liquid, yet only one species, the minute bacillus, was found distributed throughout the blood and tissues. The living mouse seemed to be a culture-medium for isolating these from the other varieties, to whose growth the animal's tissues were less perfectly adapted. In the second or third mouse successively inoculated only the specific bacilli were found.

By methods essentially similar, Koch demonstrated the association of a form of septic infection of mice, which he denominates malignant œdema, with a micrococcus species; of septicæmia in rabbits with a bacterium; and of pyæmia (with metastatic abscesses) in the latter animal with a micrococcus variety. Yet, although the fact of association was amply demonstrated, there still remained the possibility of objection that the essential agent in the infection was a soluble, unorganized substance contained in the putrid liquids and the infectious tissues used for inoculation, the bacteria being the result and not the cause. The final demonstration to the contrary, the proof that these different effects could be induced by inoculation with the respective bacterial varieties after complete isolation from accompanying animal tissues by cultivation upon solids, was not furnished at the time of this publication by Koch, but has been subsequently completely established by Koch, Gaffky, and Löffler in the laboratory of the German Health Bureau, for the bacilli of mouse- and the bacteria of rabbit-septicæmia. The extreme accuracy and critical supervision of manipulations, the logical sequence of methods, and withal the unpartisan candor and earnest desire for truth evident throughout this work of Koch's, inspired at once a confidence which has not as yet been diminished or betrayed. It is worthy of note that the infectious disease of mice described by Koch as malignant œdema is identical in clinical and pathological appearances with that which Pasteur ascribes to his "vibrio septique;" while the pyæmia of rabbits corresponds accurately with the purulent infection which, according to Pasteur, follows the injection of his microbe of pus. These results, obtained quite independently by two observers, using different methods, have been confirmed not only by Gaffky and Löffler, but also by Rosenberger in Würzburg, in a series of carefully performed experiments.

A review of the evidence already considered shows, then, that infectious diseases, identical in clinical and anatomical appearances with the various forms denominated septicæmia in man, have been induced in the mouse and rabbit by inoculation with animal tissues in various stages of putrefaction; that the resulting infection is just as certain if the putrid substances be previously boiled and thereby deprived of living organisms (Panum, Bergmann, Rosenberger). On the other hand, it is certain that *per se* innocuous culture fluids—infusions of beef, etc.—acquire, after inoculation with minute quantities of infected blood or tissue, the same septic properties, provided such blood or tissue contain living bacteria; it is further certain that this multiplication of the septic substance in such liquid is a concomitant of the vital action of the organisms therein contained (Pasteur, Koch, Rosenberger); it is further demonstrated that these organisms can and do, not alone multiply the septic material, but when isolated by successive cultures from all the accompanying animal tissues, induce, independently, fatal infectious disease (Pasteur, Koch, Löffler, Gaffky, Rosenberger).

The same principle—vital activity of bacteria—permeates all these phenomena; for the artificial induction of septic diseases has been, in all these experiments, originally accomplished by the incorporation into the animal of *putrid tissues*, with or without bacteria. Now, since putrefaction must be regarded, in the present state of our knowledge, as impossible without the presence of these organisms, it is evident that sepsis, putrid infection, was in every case due, directly or indirectly, to the action of bacteria; since even the boiled substances used by Panum and Rosenberger, and the sepsin obtained from rotten yeast by Bergmann and Schmiedeberg, had acquired their septic properties through putrefaction, *i.e.*, through the action of bacteria. Hence we are logically driven, by all this work, to the belief that septicæmia implies the introduction into the animal either of living bacteria, or of a substance which has acquired noxious properties through previous vital activity of these organisms.

More recent experiments have demonstrated, however, that the etiology of the group of clinical and anatomical appearances known as septicæmia is by no means restricted to putrid infection. In the researches as to the nature of blood coagulation, instituted by Schmidt, of Dorpat, and his pupils, it was noticed incidentally that the introduction or production in the blood of fibrin-ferment in considerable quantity produces effects identical with those of putrid infection—septicæmia. In this case the result is of course attributable to coagulation of the blood. Similar phenomena were observed by Köhler, Angerer, Naunyn, and Francken, to follow intra-venous injection of fresh blood-serum (containing therefore both fibrinoplastin and ferment), of hæmoglobin solution (which is known to favor the formation of fibrin-ferment in the blood); of sulphuric ether (which sets free hæmoglobin and hence indirectly fibrin-ferment). Injected in large quantities, these substances caused immediate death by instant coagulation of the blood in the heart and large arteries; after smaller quantities the animals survived hours or days, and exhibited the usual symptoms of septicæmia; their blood contained free fibrin-ferment, while that of healthy animals does not. Finally, Edelberg, working under Schmidt's direction, established clearly that the injection of fibrin-ferment alone, isolated from other ingredients of blood, can induce the same phenomena.

In a series of experiments communicated to the Congress of German Surgeons, in 1882, Bergmann observed the clinical and anatomical features of septicæmia—fever, swelling of spleen and lymph-glands, gastro-intestinal inflammation, cardiac weakness, ecchymoses in mucous and serous membranes—after the injection of the physiological ferments, pepsin and trypsin, in small doses; large quantities induced, like fibrin-ferment, immediate death by coagulation of blood in the larger vessels.

Raynaud and Lannelongue inoculated rabbits with saliva from a child dead of rabies, and induced thereby an infectious disease, terminating fatally in forty-eight hours or less. Pasteur found in the blood of these animals a bacterium which he regarded as the cause of the disease. Inoculation of rabbits with saliva from children dead of broncho-pneumonia caused the same result, and produced the same figure-of-8 bacterium. The same organism was found in the saliva of a healthy adult. Sternberg found that injection of fresh saliva from certain healthy individuals caused a similar fatal infectious disease, which he calls septicæmia, in rabbits, characterized by the presence of a micrococcus apparently identical with Pasteur's; and asserts that this organism, isolated by flask cultures, induced the disease again upon subcutaneous inoculation. Neucki and Gantier isolated from saliva a substance capable also of producing fatal infection of certain animals. Saliva, then, can also induce septicæmia, not only after death of the subject, but even fresh from the living individual. Whether the effect shall be ascribed to a contained bacterium or not is immaterial to our present purpose, which is to emphasize the fact that the group of phenomena called in general septicæmia may follow other causes than putrid infection; may be induced on the one hand by the vital action of isolated bacteria, and on the other by unorganized substances—the boiled septic materials of Panum and Rosenberger, the sepsin of Bergmann, the fibrin-ferment of Edelberg, pepsin and trypsin of Bergmann, hæmoglobin, etc.

The mode of action common to several, at least, appears to be the liberation of fibrin ferment; for the blood of septicæmic animals is characterized by the presence of free ferment, which is not found, unless perhaps as traces, in normal blood. This ferment seems to arise, according to the researches of Schmidt, in the disintegration of white blood-corpuscles; and these are known to be invaded and apparently disintegrated by bacteria, in the septicæmia of mice and rabbits, at least. It would appear, although not for all cases demonstrated, that the clinical and anatomical features common to the various

forms of septicaemia are attributable to the rapid liberation of fibrin ferment in the blood; and that any agent—organized or unorganized, putrid or fresh—capable of effecting such liberation may induce the disease.

This conception, at any rate, enables us to understand much that is otherwise perplexing. Various have been the attempts, for example, to explain the so-called aseptic wound fever, which occurs in the majority of severer wounds, even under the most perfect Lister dressing. Küster and Sonnenburg ascribed it to absorption of carbolic acid; but extensive experiments upon man, as well as the lower animals, have proven that the acid does *not* cause fever; but induces, on the contrary, after slight, brief, and by no means constant elevation, a decided depression of temperature. Others have referred the phenomenon to absorption of chloroform—a hypothesis incompatible with the fact that wound fever follows operations performed without anaesthesia (as is so often done in Germany and Austria) as usually as those done under chloroform. The more general opinion, that aseptic wound fever differs from sepsis,—*i.e.*, putrid infection—in degree rather than in kind, meets a serious objection, as Gussenbauer remarks, in the fact that the former occurs within a few hours after the infliction of the wound, before decomposition and consequent sepsis can be reasonably presumed to have occurred.

The clinical facts—(1) that a large minority of wounds, severe as well as slight, are followed by no fever under the Lister dressing, as was the case in over three hundred of a thousand reported by Volkmann and Genzmer, and in nine of twenty-four most carefully observed by Edelberg; (2) that the course of subcutaneous fractures without extravasation of blood is usually afebrile, while similar fractures with extensive blood extravasation often induce fever; (3) that the application of a tight bandage to a wound or fracture, which must cause some extravasation of blood, is often followed by fever in a patient previously afebrile (Edelberg); (4) that the blood of patients during simple surgical fever sometimes contains free fibrin ferment in appreciable quantities—such facts indicate that a septic wound fever is caused by absorption from extravasated blood, especially since it has been demonstrated, as already remarked, that blood, fluid or coagulated, hæmoglobin, or even isolated fibrin ferment can experimentally induce the same phenomena. It is further conceivable, though not demonstrated, that the products of a local inflammation, or the modification of cell-activity through fatigue or emotion, may also be directly responsible, through destruction of leucocytes and liberation of fibrin ferment, for some of those cases of spontaneous septicaemia which we ordinarily ascribe to unperceived entrance of bacteria or putrid products into the body.

Septicaemia is, then, a collective name for processes more or less similar, but etiologically distinct—at least, in certain lower animals; any one of several unorganized substances, any one of several bacteria (at least, three in the case of the mouse) may induce characteristic symptoms. It has been proposed to adopt the term *sapraemia* for putrid infection without bacteria, retaining the usual name to indicate the effect of organized agents; yet the clinical distinction is probably rarely possible.

The clinical experience of all ages has unanimously ascribed the second type of septic infection—characterized by chills, a remittent or intermittent fever and the formation of multiple abscesses—to absorption from pus; and it has always been designated by a name—pyæmia, purulent infection—indicative of this supposed origin. The discussion of the relations of bacteria to pyæmia begins, therefore, naturally with the consideration of their relations to suppuration. That these organisms should exist in pus exposed to the air, as in other albuminous liquids under like conditions, was *a priori* probable and long ago demonstrated; that they exist also in the pus of abscesses which have never been opened, has been conclusively demonstrated by Klebs, Nepveu, Rind-

fleisch, Waldeyer, Cheyne, Ehrlich, and especially by Ogston, who found micrococci in every one of seventy previously unopened acute abscesses, though rarely in chronic, cold abscesses.

The mere fact of association does not, of course, necessarily prove a causal relation of the organisms to the suppurative process; but the observation that a zoöglæa mass of micrococci is often the centre of an abscess; that indeed abscess-formation in all stages, from a simple accumulation of straggling leucocytes to the fully developed destructive infiltration of tissue, has been observed around a nucleus consisting of a minute embolus composed entirely of micrococci; that the progressive purulent infiltration of the surrounding tissue is preceded by an invasion of the same by micrococci—can be impartially and satisfactorily explained, in the present state of knowledge, by no other hypothesis than that the micrococci *cause* the suppuration. Experimentally there is direct evidence to the same effect.

Pasteur saw, after cultivation of a micrococcus found in ordinary water, that the injection of a few drops of the previously harmless culture-fluid, now containing myriads of micrococci, was invariably followed, in the rabbit, by suppuration around the point of injection, the pus and tissues containing numbers of the same organisms. The intra-jugular injection of the same fluid caused multiple abscesses in the internal organs. He found the same micrococcus in pus from cases of puerperal fever. Klebs, Zahn, and Tiegel found that while the injection of pus from a pyæmic abscess or putrid fluid was followed by local suppuration and multiple abscess formation in the infected animal, the same pus or liquid, after filtration through clay cylinders—whereby the bacteria were separated from the liquid—caused intense general infection, but no suppuration, even at the point of injection. Koch observed also the constant association of a characteristic micrococcus with infectious suppuration in the rabbit after putrid inoculation.

It appears, therefore, impossible to evade the conclusion that suppuration can be and is induced by micrococci. That this effect is induced by one or more specific varieties of these organisms seems probable from these researches of Klebs, Koch, and Pasteur; that it is not induced by *all* species is apparent from the fact that colonies of micrococci are frequently present in the human and other animals during various morbid processes in which suppuration does not occur—as in

Fig. 6.—*Actinomyces bovis*, tongue of ox. $\times 140$.

erysipelas. As to the mode in which this influence is exerted, there is no definite knowledge: the assumption that the deleterious effect results from changes in the chemical constitution of the containing medium, as an essential feature of the vital activity of these organisms, is supported by analogy with the processes of fermentation and putrefaction, by the phenomena known to attend the life of other bacteria, and by the direct observations of Koch and Pasteur.

Yet the induction of suppuration is not a monopoly of

micrococci: the growth of the *actinomyces bovis* in the tissues is accompanied by the formation of abscesses; upon microscopic section the fungus is found constituting the nucleus of a miliary abscess; and inoculation with the isolated actinomycetes proves that the fungus itself, and not a hypothetical soluble substance accompanying it, is responsible for the suppuration. Experimental researches upon suppurative keratitis by Leber, of Gottingen, make it highly probable that another bacterium, the leptothrix of the mouth, and a mould fungus, *aspergillus glaucus*, can also induce suppuration. On

Fig. 7.—*Actinomyces bovis*, and pus corpuscles. $\times 260$.

the other hand, several bacterial varieties are known to inhabit at times human and other animals without causing suppuration—the bacillus anthracis, for example.

The school of pathologists of which Weigert is a prominent exponent, has been inclined to regard micro-organisms not merely as a cause, but as the sole cause of acute suppuration. This view was certainly incompatible with many clinical observations, and has been recently quite dissipated by experimental research. Uskoff, under Ponfick's direction, has shown that the subcutaneous injection into rabbits of turpentine oil, is followed by the formation of pus in which no bacteria can be detected; an assertion which has since been corroborated by others. The most accurate and conclusive experiments in this direction were recently made by Dr. Wm. T. Councilman, of Baltimore, in the laboratory and under the direction of Cohnheim. Councilman made a number of glass capsules, heated them to redness, poured into each, while still hot, a boiling mixture of croton and olive oil, and sealed the open end in the flame. Fourteen of these were inserted, with antiseptic precautions, under the skin, at various places, in different rabbits. In no instance was suppuration or even adhesive inflammation observed—the capsules remained freely movable in the subcutaneous tissue. After intervals varying from two to fourteen days, when the incision wound was firmly healed, the capsules were broken subcutaneously, by force applied to the skin; in every instance suppuration followed in a few hours. An examination of the pus and abscess walls revealed nothing that could be recognized as bacteria.

Chronic or cold abscesses may have a different etiology—their clinical history and appearances, and the fact that they seldom cause pyæmia, would point to that conclusion. It is significant that of eighteen chronic abscesses, Ogston—employing the most approved technique—could detect bacteria in but four, which were consequent, moreover, upon erysipelas, typhoid fever, pharyngitis, and pulmonary consumption, respectively; in the remaining fourteen, both microscope and attempts

at cultivation gave only negative results. Their absence at the time of examination does not exclude the possibility of their presence at an earlier period of the process; that they may have lost their vitality, and with it their power to absorb the coloring agents.

Suppuration must be regarded, then, as indicating the presence of an element foreign to the living animal cells; which may be introduced directly, like the croton oil in Councilman's experiment, or indirectly as an incident in the life of various fungi. That a derangement of cell-nutrition, local gangrene, may by mechanical or chemical irritation, without the presence of other organisms, effect the same result, seems probable in view of clinical experience, but is not yet experimentally proven. Practically, we may regard acute suppuration as proof of the access of external irritant matter, organized or unorganized; and clinically, we must agree with Cohnheim, that suppuration not due to bacteria or other fungi is extremely rare. The comparative rarity of pus-formation under the Lister dressing—although this is, at best, an uncertain means of excluding organisms—is highly significant of the relations between the two.

That form of septic infection known as pyæmia is distinguished by abscess formation in external organs—from which fact alone it is evident that bacteria must play an essential part in the disease. Yet there is abundant direct evidence to the same effect: these metastatic abscesses always contain bacteria; these organisms exist not simply in the pus and in the inflamed tissue constituting the abscess wall, but also in a zone external to the territory already involved in inflammation; the invasion by organisms may therefore apparently precede the inflammatory re-action; further, incipient inflammation and suppuration are observed around minute emboli consisting of micrococci; and finally, although thrombosis and embolism occur in various pathological conditions, no suppuration occurs in such fibrinous masses, nor in the adjacent tissues, unless bacteria also be present. These anatomical facts are quite in accord with the independent evidence of experimental research. Panum found that the injection into the jugular vein of minute balls of wax or mercury caused the formation of emboli in the lungs, but that no suppuration occurred around them; he then combined embolic formation with putrid infection by the injection of putrid fluids just before or just after the formation of emboli, through the incorporation of wax, mercury fibrin or cheese particles; and varied the experiment by the artificial induction of superficial phlegmonous inflammation, in the course of which the formation of emboli was secured by injections as before. The result was always the production of simple, non-suppurating embolic masses; the substitution of fresh blood-clots for the wax, mercury, etc., whereby a closer approximation to the natural embolic process was secured, gave the same results. Emboli caused by intra-venous injection of particles of putrid flesh, however, were promptly followed by suppuration. Other experimental researches into the formation of embolic (metastatic) abscesses—by Virchow, Billroth, Weber, Waldeyer, Cohnheim—confirmed these results of Panum; putrid emboli always softened and excited suppuration; others rarely; it was further established (Waldeyer) that puriform softening of a thrombus can be caused by contact of pus or putrid matters with the external surface of the containing vessel, as well as by admission to its lumen. Since suppuration in the immediate vicinity of a vein may cause inflammation and thrombus formation in the vessel, it is apparent that phlebitis, puriform softening of thrombi—in short, pyæmia—may occur without any artificial solution of continuity in the vascular walls. Experiment has always shown that fluids (pus and putrid matter) capable of inducing pyæmia, lose by boiling (Panum, Bergmann, Pasteur) or by filtration (Klebs, Zahn, Tiegely) this power to cause metastatic suppuration—pyæmia—though still able to induce rapid and fatal infection—septicæmia. Since by these measures—boiling and filtration—the contained

organisms are destroyed or eliminated, experimenters are unanimous in ascribing the induction of metastatic abscesses to bacteria.

The clinical evidence is almost as strong; for, according to the unanimous assertions of eminent surgeons—Nussbaum, Volkmann, Esmarch, Thiersch, Verneuil, Schede, Gussenbauer, for example—pyæmia is practically unknown after wounds which have been treated from their inception by the Lister method, the avowed object and essential feature of which is the attempt to exclude organisms.

Perhaps the strongest clinical evidence of the septic influence of bacteria is afforded by the cases of so-called spontaneous pyæmia, where no suppuration nor solution of continuity is detected. In many of these a closer search would doubtless reveal a possible source of purulent infection. Weichselbaum has recently called attention to fatal cases of this kind in which the focus of infection was found as suppuration in the nose and antrum. Yet there still remain numerous cases in which pyæmia appears to proceed from deeply situated abscesses, which can have had no direct communication with the external world—after subcutaneous fractures, for example; and still another class in which a general infection without local suppuration during the first few days occurs without exciting cause, unless perhaps exposure to cold; and until the appearance of pus in the joints, etc., cannot be distinguished from acute rheumatism or from other infectious diseases. To this category belong cases of acute osteomyelitis and ulcerous endocarditis. The blood and metastatic abscesses contain in these cases also the usual micrococci; the history presents, in fact, nothing unusual except the obscurity of the infection. In some of these—as in one of osteomyelitis reported by Gussenbauer—the bacteria were observed in the blood and in the bone-marrow before suppuration had occurred; the general infection preceded the local affection. Such cases must incline us decidedly to the view that the micrococci caused not only the local suppuration, but also the primary general infection. It is noteworthy that such cases of primary pyæmia often follow exposure to cold; perhaps we should regard the retention of certain material in the blood, this interference in excretion, as a predisposing moment which has favored the development of organisms; diabetic patients certainly are especially prone to local gangrene and septic infection after a wound, and it is equally well known that a minute incision, even needle-puncture of the dropsical skin in amyloid degeneration of the kidney, exposes the patient to erysipelas and pyæmia. Yet in some cases the bacteria essential to pyæmia can and do exhibit their vital activity in the human body without the pre-existence of any recognizable deviation from the usual health, and without any discoverable solution of continuity in the integuments.

In this discussion I have assumed the etiological identity of the septicæmia and pyæmia of man with that of processes marked by the same clinical and anatomical features in animals. To such assumption objection may be made, based on the known differences in the effects produced on man and other animals by the same toxic agent; rabbits, for instance, live and fatten on a diet of belladonna leaves, and carnivorous animals are but slightly susceptible to anthrax. But when we consider that the septic processes of man are objectively identical with those of other animals, that they result in various animals alike from putrid and purulent infection, and furthermore, that they have been induced in animals by direct inoculation from the human subject, we must justify the application to man of the principles ascertained from the study of these septic diseases in other animals.

Although our present knowledge of the etiology of septic infection is thus incomplete, our ability to prevent such infection is fortunately more satisfactory. For we may practically classify all such cases into two categories—those in which a possible source of infection

is previously apparent, and those in which no such source is discoverable. The treatment of the former class, the large majority, comprising all wounds, I may be permitted to discuss in so far as the principles of such treatment are based upon a recognition of the agency of bacteria in the morbid processes. Septic infection from a wound means the absorption through that wound of one or more constituents of the putrefactive process. Now, putrefaction is impossible without bacteria; hence septic infection implies the vital activity of bacteria, past or present. The actual presence of bacteria in the wound is, as has been shown by Panum, Bergmann, and others, unnecessary—septicæmia may be induced by putrid liquids deprived of bacteria; *but these liquids are putrid*—they embody the products of bacterial life. Precaution against the introduction into a wound of already formed poisons—by disinfection of hands, instruments, sponges, etc., on the side of the surgeon, and by similar cleanliness as to the body of the patient, is evidently the first measure against sepsis—a measure quite overlooked occasionally by surgeons who intend to use all so-called antiseptic precautions. I once saw a laparotomy made by a rigid apostle of Listerism; the carbolic spray was used; hands, instruments, ligatures, etc., thoroughly carbolicized; but the patients' skin was not even washed; several coils of intestine were in course of the operation laid upon the skin, and came in contact with the pubic hair. The operation itself was not serious, but the woman died of purulent peritonitis.

If no infectious matter be thus carelessly introduced from without, the occurrence of sepsis from a wound necessarily implies decomposition in the wound itself. For the accomplishment of such decomposition it is evident that three factors must concur: 1, the presence of animal tissues deprived of vitality, and hence capable of putrefaction; 2, the presence of organisms capable of inducing putrefaction; 3, the prevalence of conditions which permit the vital activity of these organisms. The absence of any one of these conditions renders putrid infection impossible. We are familiar with analogous phenomena outside of the body. Urine or blood in free contact with ordinary air putrefies; if access of bacteria be prevented by closing the mouth of the test-tube with cotton, etc., putrefaction does not occur; the process can be prevented with equal certainty by changing the environment—addition of alcohol for example—whereby the vital activity of bacteria is arrested. We have abundant evidence, as has been already stated, that the same principles prevail within as well as without the living animal. That the bacteria ordinarily present in the air are powerless to destroy living tissues is proven by the fact that unfiltered ordinary air has been passed for hours through the peritoneal cavity of rabbits without inducing pathological changes—indeed, the entire subcutaneous tissue of animals has been inflated with air with like result; by the harmlessness of surgical emphysema; by Hiller's injection of such bacteria into his own body, etc. That the presence of putrefiable substances, if excluded from these same bacteria, gives rise to no putrefaction nor sepsis is shown in the cases of intra- and extra-uterine pregnancy, where a dead foetus is carried for months or years.

The prevention of decomposition and consequent septic infection from a wound can therefore be accomplished theoretically in any one of three ways: 1, the exclusion of putrefiable materials, *i.e.*, cleanliness; 2, the exclusion of bacteria; 3, the addition of a substance in whose presence putrefactive bacteria are inert.

It is evident that the accomplishment of any one of these three ends is antiseptic, or, if you prefer on etymological grounds, aseptic surgery. There is a prevalent inclination to consider Listerism and antiseptic surgery as synonymous terms; and to regard the success in avoiding sepsis which is secured by other methods—the open air and simple water dressing, for example—as proof not only that the Listerian details are unneces-

sary, but also that the agency of bacteria in the induction of sepsis—an agency which the Lister method was devised to defeat—is a myth, a mere craze, a fashion. It is manifest, however, that antiseptic surgery is far more comprehensive than Listerism. Listerism aims chiefly at but one of the three possible ways for the prevention of sepsis—the exclusion of ferments; the very methods whose success has been considered proof of the fallacy of antiseptic surgery demonstrate practically what is self-evident theoretically, that putrefaction and putrid infection from a wound can be prevented by the removal of putrefiable materials, just as certainly as by the exclusion of organisms. The aseptic success of Savory and Lawson Tait—rivaling that of Volkmann, Esmarch, and Lister, was secured by the most scrupulous care in avoiding the retention or accumulation of any discharge in the wound. The result is asepsis, the means a *pe* ic.

That this method of preventing sepsis affords the same certainty of success and possesses the same range of applicability as the Listerian, I would not maintain; indeed, my own limited experience, including some observation of surgery in St. Bartholomew's Hospital, inclines me to the contrary belief. I would merely protest against the not infrequent assertion that Savory's and Tait's success in avoiding putrid infection is an argument against the demonstrated agency of bacteria in the induction of sepsis.

There still remain a considerable number of cases, notably wounds of mucous membranes, in which anatomical relations prevent the execution of either of these aseptic methods: bacteria cannot be excluded, nor perfect cleanliness of the wound secured. In such cases asepsis can be theoretically obtained very simply by the presence of some substance in the wound which renders vital activity of bacteria impossible. There is a great variety of such agents—alcohol, carbolic acid, etc.—but for these cases all such are, from their volatility or solubility, practically useless; and it was reluctantly admitted on all sides that operation wounds involving mucous membranes could not, generally speaking, be rendered aseptic with certainty. Between 1860 and 1880 Billroth performed the amputation or extirpation of the tongue one hundred and nineteen times on one hundred different individuals; and notwithstanding the most careful attention, including frequent syringing with solutions of potassium permanganate, carbolic acid, or other antiseptic, twenty-six of these patients died, nearly all from septic infection, either directly from the wound or indirectly through the inhalation of septic products—"schluckpneumonie." With the introduction of iodoform into surgery the long-sought substance was found—comparatively insoluble and non-volatile—in whose presence the ordinary bacteria do not multiply. Under the proper use of iodoform wounds of mucous membranes are as secure from decomposition and septic infection as an amputated stump under a Lister dressing. This is admitted even by the fiercest opponents of iodoform—those who, like Kocher of Berne, having ignorantly poisoned their patients with it, would transfer to the agent the odium which evidently belongs to themselves. In 1880-81 Billroth made eighteen tongue extirpations, packing the wound with iodoform gauze which was allowed to remain undisturbed five to seven days, then sometimes renewed. Not a single septic infection occurred; recovery followed in every instance.

An operation which, though not *per se* formidable, had, even in Billroth's skilful hands, been followed by a greater mortality than that attending ovariectomy, was deprived of its septic terrors. I would particularly recommend this to the consideration of those who ignore all experimental work, who admit as worthy of consideration only clinical results, and who regard the success of Savory and Tait as the overthrow of aseptic surgery in particular, and of bacteria in general. Here is aseptic surgery *par excellence*, though the spray, protective

mackintosh, and attendant paraphernalia are absent; here is the prevention of septic infection by measures which do not exclude bacteria from the wound, but simply restrain their development. The method of Lister, conceived and devised upon a hypothesis, before the assumptions of that hypothesis had been verified, contained, as subsequent developments demonstrated, some errors of conception and execution. The spray, for example, that sign-manual of Listerism in the professional mind, seems less essential since we have learned that bacteria are less numerous in the atmosphere than was formerly supposed; and when we consider the researches published by the German Health Bureau, it seems somewhat doubtful whether the carbolic acid spray ever killed a single healthy bacterium; the vitality of certain spores is certainly not thereby affected. Koch found that the spores of anthrax bacilli, for example, retained their power of development after immersion for seven days in a two per cent., and after twenty-four hours in a five per cent. solution of carbolic acid; yet the bacilli lost their vitality after two minutes' contact with even a one per cent. solution. The clinical results also support the assertion that irrigation of the wound accomplishes quite as effectually the object for which the spray was designed. Yet it must be admitted that except in those cases, such as abdominal sections, where the spray causes positive and decided injury, there is a *possibility* of benefit from its use.

For application to the wound, many substitutes have been proposed for the objectionable carbolic acid: Fischer employs naphthalin; Schede and others report excellent results from corrosive sublimate; Langenbeck and Billroth regard iodoform as satisfactory.

To secure cleanliness—freedom of the wound from all putrefiable materials—surgeons now more generally appreciate the importance of ligating or twisting every vessel, however small, which could bleed when, with the discontinuance of the anæsthetic, the heart's impulse becomes stronger. The application of a firm, even, elastic bandage over the lips of the wound is often used, also, to accomplish the same object. For absorption of putrefiable materials Esmarch has used with great satisfaction turf enclosed in gauze bags; Schede is pleased with sand, previously heated and soaked in corrosive sublimate solution, which is poured directly into the wound. Perhaps one of the most important of antiseptic measures is the deep closure of the wound; whenever the lips of the wound are thick—as in abdominal sections and thigh amputations—the use of silver wire and lead plates for approximation of the deeper surfaces is essential to prevent the accumulation of blood in the pockets otherwise present, and the consequent danger of sepsis.

Antiseptic surgery, then, is not comprised in the spray and carbolic acid; it is not simply a question as to the relative anti-bacterial properties of this, that, and the other so-called antiseptic agents. It is an attempt to prevent the entrance into, as well as the formation within, a wound of all substances, organized and unorganized, which can interfere with cell-nutrition. It comprises, first, the exclusion or removal of all putrefiable materials—blood, pus, necrosed tissue (a point to which the Listerian school seems inclined to ascribe a subordinate place; witness Cheyne's "Antiseptic Surgery"); second, the exclusion of all ferments, bacterial or other; and, since neither of these can always be accomplished, since even under the most perfect Lister or other dressing, both putrefiable materials and bacteria may be present; third, the establishment of conditions incompatible with bacterial development. The most complete antiseptis is evidently not that which sees in bacteria the sum and substance of all surgical evil, but that which recognizes and endeavors to avoid *all* possible sources of infection. The most perfect realization of this ideal which it has been my fortune to witness, is seen, not in King's College Hospital, but in Billroth's clinic. Sponges are prepared by the abstraction of fat and sand,

and by at least fourteen days' immersion in five per cent. carbolic acid solution, in which they remain until used; for the operation they are put in two per cent. solution; ligatures (Billroth generally uses silk) are also kept in a similar solution. The skin at and around the location of the proposed incision is shaven, scrubbed with a flesh-brush and soap, and washed with carbolized water; hands and instruments are most scrupulously cleansed; operator and assistants wear clean linen dusters; no spray is used. Every bleeding point, however small, is caught temporarily in a clamp forceps, and at the close of the operation, ligated at the end of the severed vessel, to diminish the amount of necrotic tissue; the surface is thoroughly irrigated with three per cent. carbolic solution; a little powdered iodoform is often dusted into the wound—not, however, if immediate union be expected. If the soft parts severed be thick, the lips of the wound are approximated deeply by silver wires, and superficially by closely set silk sutures. The Esmarch bandage is removed from the limb—in amputations—as late as possible, since absorption does not occur so long as the bandage remains, but begins very actively so soon as the circulation is restored. A strip of iodoform gauze, usually also some powdered iodoform, is applied to the seam; then several layers of iodoformed or carbolized gauze; finally a very firm roller, starched organdine, or even elastic bandage is tightly applied over the lips of the wound. The first dressing remains unmolested as long as possible, the time varying, of course, with the case.

TWO ATTACKS OF SCARLET FEVER IN THE SAME INDIVIDUAL WITHIN A PERIOD OF EIGHT MONTHS.¹

By FRANCIS P. KINNICUTT, M.D.,

PHYSICIAN TO ST. LUKE'S HOSPITAL, AND TO THE OUT-PATIENT DEPARTMENT, NEW YORK HOSPITAL.

ON April 15, 1882, M. W.—died of scarlet fever. On the 19th her brother, aged five years, was taken ill with the same disease. There was severe angina; the exanthem was very profuse, involving the entire body. There was marked delirium with the maximum development of the eruption. The temperature maintained a high range throughout the first week, varying between 104° and 105° F. (axilla). The subsequent desquamation was very extensive, and of the characteristic lamellar type. Unilateral inflammation of the middle ear, with perforation of the membrane, occurred, and moderate albuminuria was developed in the second week, which disappeared two months later. The patient was confined to his room for seven weeks. He was in good health during the summer and autumn.

On the 31st of the following December the patient suddenly became indisposed, and an examination a few hours later showed a slight congestion of the fauces and a swollen submaxillary gland; the temperature was 102° (axilla), and there was vomiting. The diagnosis of scarlet fever was not entertained at this time. Thirty-six hours later, however, an abundant and typical scarlet fever exanthem appeared about the neck, which rapidly spread, and in a few hours involved the entire body. The eruption reached its maximum development on the fourth day, with a temperature of 104° (axilla), and, if possible, was more profuse than on the former occasion. The manner of fading was characteristic, and a most abundant lamellar desquamation followed in the second week. The affected gland suppurated and was opened; slight albuminuria appeared at the beginning of the third week, which still persists. The patient has since suffered from a copious eruption of boils on various parts of the body.

On the 14th of January the grandmother of the patient, who had been in constant attendance in the sick room, was taken violently ill with facial erysipelas, which defervesced on the seventh day.

Remarks.—Recurring attacks of slight angina, with or without a somewhat rudimentary exanthem, in individuals exposed to scarlet fever contagion, who have previously suffered from a characteristic attack, are of comparatively frequent occurrence. True *relapses*, in which the characteristic eruption has reappeared during or at the close of desquamation and has again run its course with renewed fever, have been reported by several observers.

A second infection of scarlet fever, occurring within the short period of eight months, in which all the characteristic symptoms are manifested with as much prominence as in the primary attack, is sufficiently rare to be worthy of record. I have only been able to find similar cases recorded by West and Hillier (one case after thirty-six days), Laudeutte (two months), Holst and Wetzler (three months), Salzmann (five months), Easton and Trojanowsky (six and nine months). In the case reported above, the two attacks were of quite similar intensity, and were in all respects very typical.

The apparent slight susceptibility of other members of the family to the poison (the remaining children, three and nine years of age respectively, without previous infection, did not contract the disease, although fully exposed on both occasions), and the development of a facial erysipelas in an attendant upon the patient, are additional points of interest in the case.

TRANSPLANTATION OF PORTIONS OF THE CONJUNCTIVA FROM THE RABBIT TO THE HUMAN EYE—ALLOPLASTY.

By HENRY D. NOYES, M.D.,

NEW YORK.

THE above proceeding has recently attracted attention, and I beg leave to report my experience with it. I will premise by stating that the operation was originated by Mr. Wolfe, of Glasgow, in 1872, and he gives a full account of it in his recent book on "Diseases and Injuries of the Eye," page 58, 1882. Many European surgeons have done the operation, but in this country it has, so far as my information goes, not been extensively imitated. Soon after it was announced, I made trial of it, and Dr. W. S. Little, whose case has recently been published, when he was my assistant in the New York Eye and Ear Infirmary during 1873-4, aided me on more than one occasion. I do not find a record of my earliest operations, but since 1878 there have been seven operations done at the Infirmary, of which one was performed by Dr. Callan and six were performed by myself. In the majority the lesion was symblepharon caused by burns of the eye, but about four years ago I employed the method to increase the size of the conjunctival sac, that a patient might be enabled to wear an artificial eye. I shall not attempt to relate the cases in detail, but shall state what experience has taught me in certain particulars.

The necessary dissection is first performed to remove all adhesions or deformity, and in the case of symblepharon to give the eyeball and the lids their proper freedom. For preparation of the conjunctival sac to make room for an artificial eye, incisions must be made as the peculiarity of the case may require. I have found that black rabbits are to be preferred to white, because in them the conjunctiva is firmer and can therefore be more easily handled.

The animal can be best controlled by having him in a pasteboard box, out of which his head protrudes through a closely fitting aperture. He should be etherized, but the anæsthetic need not be freely given. To dissect off the conjunctiva, I have in my last two cases begun by splitting the inner canthus, turning back the angles thus formed and stitching them temporarily to the adjacent skin. At the edge thus cut the dissection is begun, and

¹ The patient was under my personal observation throughout both attacks.

in taking up the conjunctiva the semilunar fold or third eyelid with its contained cartilage is lifted. I do not attempt to cut out the cartilage; I simply trim it as needful when the whole has been taken up. The dissection may include the conjunctiva of both lids and should be conducted from the circumference toward the cornea. It will not usually be needful to take more than half the membrane. I have found a pointed pair of scissors, curved on the flat, to be the best instrument. As the membrane is lifted, two threads of fine black silk with needles attached to them, should be put into one end of the piece and by these, when fully separated, it will be carried. The utmost care must be exercised to avoid snipping holes through it, and it becomes impossible to give form to the piece until later. It rolls into a mass, and the epithelial side cannot be distinguished from the opposite side except by the threads. When it has been separated I put it into a saucer of tepid water and fasten it on a submerged piece of cork by the points of threaded needles. I now trim it to proper shape. Next I carry it on the cork to the eye and run two of the threads from the piece into their places in the patient's eye. Then taking out the needles from the cork, draw their threads through the piece and pull it into its place and lay it out smoothly. I apply it to the eyeball and cover as much of the lid and globe as possible. To make the cul-de-sac, the stitches are brought through the eyelid and tied over a bit of stick on its outer surface. As many as ten stitches or more may be required to hold the piece in place. By operating in this way, a piece of conjunctiva three-fourths of an inch long and almost half an inch wide can be managed. Mr. Wolfe proceeds in a different way, which he describes as follows: "I put the patient and two rabbits under chloroform, one being kept in reserve in case of accident. I then separate the adhesions so that the eyeball can move in every direction. Next I mark the boundary of the portion of the conjunctiva of the rabbit which I wish to transplant, by inserting four black silk ligatures which I secure with a knot, leaving the needles attached. These black ligatures indicate also the epithelial surface, which would be very difficult to distinguish after separation. The ligatures being put on the stretch, I separate the conjunctiva to be removed with scissors, and transfer it quickly to replace the lost conjunctiva palpebræ of the patient, securing it in its place by means of the same needles and adding other two stitches or more if requisite."

I have found that to put the piece upon a cork under water was an easier mode of transfer than to do it directly by the threads from the eye of the rabbit. Mr. Wolfe lays the piece on the palpebral surface. I have applied it to both the ocular and palpebral surfaces. Whether any advantage can be claimed for one situation above the other, I do not know. My remarks apply, of course, to symblepharon, and usually the lower lid is at fault. In no instance have I met with entire failure while the degree of benefit has been various.

When done to make a cavity in which an artificial eye can be worn, I have caused the patient, after the parts were healed, to wear a small piece of porcelain, shaped like an artificial eye, to stretch the tissues, and have introduced larger ones as the increase in the size of the cavity would permit. In one case of a boy, twelve years of age, the result was satisfactorily accomplished in about four months. In some cases where the patients had long worn an artificial eye and the conjunctiva had grown thick and fleshy and ribbed, I have not had success in this endeavor; but if the tissue has not too greatly degenerated the case is hopeful. A condition of true xeroma, where the membrane has lost all secretory properties, is not favorable, because extreme shrinkage will occur.

The boy above mentioned had lost one eye from inflammation during infancy, and not only had the globe shrunken to a very small nodule, but the conjunctival sac had become practically obliterated. The boy

was extremely sensitive to his disfigurement, and was unwilling to go to school, because his companions made fun of him. As above stated, I succeeded in enabling him to wear an artificial eye, which, although rather small, removed the conspicuous deformity and relieved him from persecution. Unless a piece of new material had been introduced, it would have been impossible to enlarge the conjunctival cavity.

The transplantation of mucous membrane would *a priori* be regarded as more likely to succeed than would the similar treatment of large and isolated pieces of skin—an operation which Mr. Wolfe also was the first to propose. In both cases the cells of the transported tissue must for a time maintain their vitality without gaining any nutriment directly from the circulation. The more directly they can come into relations with the living tissues on which they are laid, the easier it will be for them to get a supply of fresh nutriment. At any rate, this seems a plausible supposition, and to be in favor of the better viability of mucous membrane as compared to skin. In the case of the latter, it is known to be necessary, as Mr. Wolfe pointed out, to reduce the skin to the utmost thinness. When this is done, it is found that the epidermoid layer perishes and is cast off, while only the deeper parts of the skin enter into real union with subjacent structures. In a recent case in which I have done transplantation of skin without any pedicle—to which, I think, the name of *alloplasty* may suitably be applied—the surface layers of the skin were not cast off; they seemed to undergo a kind of dry gangrene and became hard, black, and leathery. Nothing was exfoliated until six weeks after the operation. Then the dry scab dropped off, and underneath was found a well-formed cicatrix, which served the desired purpose, and removed the deformity of the eyelid, for which the operation was undertaken. It was evident that the deep layers of the inserted piece formed an attachment to the locality, and gave rise to the formation of material duly covered by epidermis. With mucous membrane no sensible separation of a living from a dead part can be recognized; yet the piece appears to undergo sloughing, which subsequent observation proves is either not a total death, or that a special activity is awakened in the surface covered by the piece which issues in the formation of a new covering material.

CONSIDERATIONS ON

ANTERIOR UTERINE DISPLACEMENTS AND A NEW METHOD OF TREATMENT FOR THE SAME.

By C. A. VON RAMDOHR, M.D.,

ASSOCIATE PROFESSOR OF GYNECOLOGY AND OPERATIVE MIDWIFERY, NEW YORK POST-GRADUATE MEDICAL SCHOOL.

In the consideration of displacements of the uterus it is necessary to understand the term "normal position." I think I cannot do better than quote the view of Richer, "*Traité clinique Martineau*":

1. In the foetus, the newborn, and the child, up to ten or twelve years of age, the uterus has neither a fixed nor a determined direction or position; it is elongated, soft, flexible, not situated in the pelvis, but in the abdomen, unprovided with true ligaments, and is easily moved by any force whatever.

2. In adult women the uterus lies though it is lightly enough fastened by its very incomplete ligaments, subject to frequent displacements backward, forward, and to the sides, mostly in one direction, which may be called *normal*; this is more or less regularly flexed forward, its axis seeming to follow the direction of the pelvic canal. Therefore, as the pelvis describes an arc, with its concavity forward, the axis of the uterine cavity is inclined the same way.

Schultze and Fritsch have enabled us to discard those

abominable representations of *pelvic sections*, still scattered through most of our gynecological and obstetric works, and which are totally inadequate to render a correct representation of what may be called *the normal position*, and they have shown that dissections of dead or frozen bodies are by no means to be relied upon to give us the absolute position occupied by the uterus during life. Hach (Dissert., Dorpat, 1877) also has demonstrated that in two cases, where a displacement of the uterus was diagnosed twenty-four hours before death, *the exact counterpart appeared in the autopsy*. The abdominal and the blood pressure, two factors in keeping the uterus in position, discontinue after death, and consequently the representations obtained by the use of frozen bodies, etc., are frequently incorrect.

The uterus is sustained, more or less, by the so-called ligaments, the vagina, and perineum below, and the excessive quantity of erectile tissue and blood-vessels surrounding it, the vagina, and ovaries.

The round ligaments come into play as supports only when the uterus is in retroversion; shortened by disease they form a grave factor for displacement.

Professor Pallen, however, has for many years denied these functions of the round ligaments, and claims that they are but the analogues of the cremaster in the male, functioning only during erotic excitement, and then for the purpose of dragging the uterine body toward the pelvic arch.

The broad ligaments, though admitting of a good deal of mobility of the fundus, before being stretched by pregnancy, contribute much to keep the organ from lateral displacement.

Posteriorly the utero-sacral (utero-lumbar) ligaments, made up of the folds of peritoneum forming Douglas' cul-de-sac, strengthened by strong bundles of the pelvic fascia, and musculo-cellular prolongations from the vagina, and from the *cortex uteri* itself (Luschka's muscle), are, after embracing the rectum, inserted into the lower lumbar vertebrae. These are the ligaments, *par excellence*, a shortening or relaxing of which will produce various displacements. Continuing forward from the cervico-corporeal junction, they embrace the bladder, and are inserted in the pubes. Besides, about two centimetres of the cervix are attached to the bladder by cellular tissue.

The firmness with which the base of this organ is fixed (by ureters, cellular tissue, etc.), and its intimate connection with the vagina and uterus, make the vesico-vaginal septum a strong factor in the circle of uterine support, especially when it is considered that prolapse without cystocele is rare or almost impossible.

This line of support, extending from the subpubic ligament to the attachment of the sacro-uterine ligament above, forms what is described by Savage as the *pelvic roof*. It is this pelvic roof which, intersecting the uterus at its cervico-corporeal junction, allows of a free tilting mobility forward and backward, but not so much upward or downward. However, the cervix is, without doubt (Savage notwithstanding) prevented from sinking downward and backward by the posterior wall of the vagina. This, again, derives its support from the prolongations of the vaginal tube to the pelvic fascia, from its own inherent rigidity, and last, but not least, from the perineum. It is obvious, then, that it is not the perineum directly, which gives support to the uterus, but indirectly, in so far as it supports the posterior vaginal wall; besides which, the posterior wall, being rather below than behind the anterior wall, also supports the latter, and with it furnishes additional safety against cystocele.

The abdominal pressure materially influences the organ. The various plexuses of erectile tissue surrounding, as they do, vagina and uterus, and being filled in life with an amount of blood sufficient to give them a certain stability, will do much to restrain the apparently superabundant mobility of the uterus (Pallen).

Normal variations in its position occur every day; the

filling of the bladder lifts the fundus, and throws it backward; an abnormally distended rectum throws the organ *in toto* forward (and only exceptionally the fundus). The act of respiration draws the organ up, or depresses it, any exertion or compression of the abdominal muscles depresses the uterus; besides, congenital malformations, such as short vagina, or one short vaginal wall, an abnormally short ligament, may, in a given case, though deviating from the more frequently found position, represent the normal one here. It is only in those malpositions where free mobility is impeded, where the ligaments are shortened or relaxed by disease, where the blood-vessels are stretched or impinged upon, and an obstruction to the return circulation takes place, concomitant with congestion or inflammation, and where, even without any of these conditions, symptoms are produced which cannot be explained except by such displacement, that we are called upon for their rectification. Kiwisch, Simpson, and Velpeau indeed imagined, and fought for the theory that displacements under all circumstances ought to be corrected; but it is only exceptionally that we meet with a case where the displacement is not the result of some other trouble, though certainly it will aggravate this state, and usually will call for treatment.

As my ultimate purpose is to explain my pessary, let us omit displacements backward, upward, and laterally, and we find that exciting causes for prolapse and anteversion (with so much concomitant flexion as not to make this an extra factor requiring treatment) are:

1. *Increased weight of uterus.* a. Tumors, subinvolution of the organ, or inflammation in prolapse. b. Increased weight of fundus, subinvolution of placental site, or fibroids of the anterior wall in anteversion.

2. *Interference with uterine supports.* a. Rupture of the perineum, prolapse of the vagina, relaxed ligaments, or flabby abdominal walls in prolapse. b. Prolapse of anterior vaginal wall and cystocele, relaxation of the utero-vesical ligament, shortening of lower part of posterior ligaments, shortening of round ligament in anteversion.

3. *Pressure from above.* a. Tumors in the abdomen, tight lacing, violent efforts, ascites, and even, as described by Breisky, the entrance of intestines into the otherwise patent Douglas' cul-de-sac.

To recognize in each given case the cause of the displacement will be our first duty. the treatment will suggest itself.

A ruptured perineum ought to be united.

An inflamed or subinvolved uterus or vagina ought, by rest and hot water, etc., to be decreased in size; false membranes ought to be stretched or ruptured; fibroids in the uterus removed if possible; tight clothing discarded; tone given to an anæmic person or lax ligaments by out-door exercise and administration of iron and nourishment. Lax or obese abdominal walls are to be kept in place by a bandage, thereby distributing the pressure of the intestines equally over the pelvic roof. But in all these cases replacement of the organ and a well-adapted pessary, lifting the organ to its normal plane so as to relieve the pressure and stretching of blood-vessels, will always prove a valuable factor, with which I, for one, would not dispense. Of course, where abdominal tumors are the cause of the displacements, or where the uterus is so firmly glued down in its abnormal position that it is impossible to stretch the adhesions, these latter means will be of no avail.

The replacement will be always easiest performed in the knee-elbow position. The aid of gravity is thus brought into force. Elevating the perineum will admit the air into the vagina, which will rectify the cystocele, prolapse, or anteversion in many cases by itself.

Slight adhesions should be stretched, and the reposition completed by the finger, or a cotton ball held by a forceps. Whenever we cannot replace by these means, it is dangerous to use the sound or elevator, the application of which, even in the other cases, is always dangerous.

We now come to those means which we have to maintain a replaced anteversion or a cystocele with prolapse in position.

I do not wish to enumerate all those appliances which take their support from outside of the vagina, from an abdominal belt and perineal band. Nothing more unphysiological could be imagined; excluding the disagreeable sensation of the band, each jar and every different posture reflects violence on the uterus, giving rise to constant irritation. The number, however, of vaginal anteversion, or prolapse pessaries devised, and daily being devised, indicate that we have not yet found our *beau idéal*.

All such pessaries aim at the elevation of the vesico-vaginal septum, and thereby of the bladder and uterus, except rings, which stretch the sacro-uterine ligaments, and thus sling the uterus up from behind.

They take their support from either the posterior vaginal wall and perineum, or from the bony parts, the symphysis, or the planes of the ischium. Those taking their support from the soft parts, produce less irritation because they do not receive so much counter-pressure, and they allow more latitude to the instrument and uterus; besides, the smaller the pessary, the less irritation it will produce, and the more chance will the relaxed tissues have of regaining their tonicity. Therefore, all those rings, elastic or inelastic, and those appliances which act merely by their bulk, and which, to maintain their efficacy, have to be constantly increased in size performing their work by stretching the whole vagina, ought to be rejected.

Thomas', Pallen's, and Graily Hewitt's pessaries are excellent for some cases; but one of the grave objections to them is, that they cannot ordinarily be removed and reintroduced by the patient herself, a defect also of that otherwise most excellent pessary of Gebrung's.

This pessary—the double horseshoe—lies, in his diagrams at least, with the lower bow below the pubic arch, while the other one supports the vesico-vaginal septum. In reality both bows work themselves behind the symphysis (a position illustrated by a diagram by Mundé) and stretch the base of the bladder, giving rise to vesical irritations or peri-uterine inflammation. To obviate these defects I have devised a pessary, a small size of which, while supporting the anteversion or cystocele completely, is easy of introduction and withdrawal, as it takes its support ordinarily from the soft parts, and is even applicable in cases where the perineum is ruptured, and cannot be operated on.

It has the form of a Smith's modification of Hodges' pessary. The upper and lower parts consist of hard rubber, and are joined on either side by a spring, coated with soft rubber. The pessary is broad for those cases where the perineum is partly wanting, while it is narrower where the latter is intact.

After the anteversion or prolapsus are replaced, the pessary is introduced like an ordinary Smith's, but the upper bar is left in front of the cervix, instead of being placed behind it, as in a retroversion. The weight and the tendency for the malposition to reoccur are neutralized by the springs, which will only give way to a certain extent; while their elasticity makes it particularly adapted for such cases where tenderness would preclude the use of any other pessary.

In a case where the uterus is heavy the springs have to be strong; where the organ is light and easily movable they have to be more yielding.

CASE I.—Mrs. W——, aged thirty; married three years;

one full-term pregnancy two years ago, easy labor; menstruated three months after confinement; has always been well up to that time; menstruation regular as to time and quantity. Complaints of pains in back and left side, which are increased before menstruation, and upon exercise; frequent micturition, less when recumbent; constipated. Physical examination reveals a uterus which measures three and one-eighth inches, and is in a high degree anteverted; severing of the perineum proper, though skin surface intact.

Thomas' and Gebrung's pessaries produced only very transient relief, the former after a while produced irritation, a small size of the latter she lost in walking; wearing a larger size was attended with discomfort.

For this case I devised my pessary. The relief it gave her was immediate; she wore it for three months, and is now pregnant for the second time.

CASE II.—Mrs. B——, aged sixty-five; widow; mother of four children, the last of which was born twenty-six years ago after instrumental labor. Since that time patient has been troubled with dragging pain in pelvis. A few years ago a tumor appeared outside of the vulva, which she has carried since then by a diaper. This has incapacitated her for any exertion, though she is otherwise hearty for her age. Physical examination revealed complete prolapse, the uterus slightly anteverted, and a lax, partly lacerated, perineum.

Reduction was easy; a broad size of my pessary kept the uterus well in place (the patient would not consent to an operation). She has worn the instrument for the last three months without any discomfort; she is able to do her housework, and only in straining at stool does she stand in danger of losing it. By applying the tip of the finger to the lower arc she can easily obviate this difficulty.

CASE III.—Mrs. S——, aged thirty-two; married seven years, three children, the youngest of which is two years old, complains of menorrhagia, dragging pain, and frequent micturition. Physical examination showed enlarged anteverted uterus, deep unilaterally lacerated cervix, and slight perineal rent. The cervix was united by four sutures and healed promptly, leaving the uterus decreased in size, and the patient free from her accustomed flooding. The pain and anteversion were not modified. The uterus was now replaced, and one of my pessaries introduced. The relief was immediate; she did not return for ten weeks, and then she gave me the following history: Shortly after the introduction of my ring she had removed to Brooklyn; she had not felt any pain until after that event. Her idea was, that the ring, which she had not until then removed, was out of place; she consequently withdrew the instrument and reintroduced it, at once alleviating her sufferings; but in a few hours, after straining, she felt the pains return. Being disinclined to come over to New York, she consulted two gentlemen in Brooklyn, both of whom tried various instruments, none of which did her any good. On examination I found her uterus heavier and lower down than before, and upon introducing my pessary [the same which she had worn before] the uterus pressed it down instead of being supported by it. An instrument with stronger springs at once set matters right. For several months she has now felt perfectly well.

This strength of the spring must not be overlooked, because in another case I have, against my will, turned an anteversion into a retroversion, by a spring too strong for that individual case. Unfortunately this case has passed away from my observation, and I cannot tell how it terminated. In four more cases my pessary has given complete satisfaction to my patients and to myself, and I feel warranted in presenting it to the profession, only hoping that it will be given a fair trial. The instrument is manufactured for me by Messrs. George Tiemann & Co., of New York, who have managed to make the movable part of the pessary perfectly smooth and hard enough not to become imbued with the secretions of the vagina.

REVIVIFICATION.

By S. WATERMAN, M.D.,
NEW YORK.

THE following two cases are selected to show the necessity of making persistent efforts at revivification in cases of sudden death, especially from heart disease, as well as in cases of still-born children.

There is no doubt in my mind that in many cases of sudden death, especially from heart disease, prompt and persistent efforts to reanimate the apparently dead person may result in restoring life. It is probable that in many instances the heart's action may fail from transient causes; a dangerous syncope may supervene, and unless timely efforts are made, and proper measures are promptly resorted to, the person may pass from a state of suspension of vitality into the silent and lasting embrace of death.

A case in point happened to me in the month of February, 1880. Mr. B—, a gentleman of sound constitution, about six feet in height, springing from a healthy ancestry, aged eighty-four years, had an attack of senile gangrene in the inguinal region, two inches and a half in length, and one inch wide. The slough was in time thrown off, and healthy granulation filled the wound. A second attack subsequently, not quite so severe, destroyed a part of the integument in the umbilical region. Its cause and final cure was similar to the first attack. The third attack was in the great toe of the left foot. The entire toe perished, but a line of demarcation formed, the destructive process went no farther, healthy granulation formed, and the healing process progressed in the most healthy and satisfactory manner. Mr. B— suffered in addition from valvular disease of the heart, and likewise from Bright's disease (granular degeneration), probably in consequence of retarded circulation and diminished blood-pressure. One morning while I was sitting at his bedside, and in friendly conversation with him, he being to all appearance in a very happy mood of mind, he suddenly fell back, his eyes became fixed and glassy, a deadly pallor crept over his countenance, respiration and the heart's action ceased simultaneously, and death seemed to have carried him off suddenly and unexpectedly.

It was this suddenness of the event that impelled me to make efforts at revivification. Two nephews of Mr. B—, who were fortunately in the house, were brought under requisition, and under my direction systematic artificial movements were carried on for nearly thirty minutes. Then, to my unspeakable satisfaction one deep inspiratory effort was made by the patient himself. Thus encouraged, we redoubled our efforts for ten minutes more; other inspiratory efforts followed in quicker succession, the heart began to respond, hardly audible at first, it required force and momentum; it could now be felt at the wrist: the deadly pallor passed away, the eyes lost their glassy, fixed aspect, sighs and groans could be heard, twitchings of muscles of arm and fingers could be distinctly felt, and the rigidity of death made way for reanimated conditions.

He lay unconscious for more than ten hours, respiration being hurried, and breathing stertorous, the heart's action wild and irregular. During the night he was delirious and restless. Toward morning all untoward symptoms subsided, and a quiet sleep followed the extreme restlessness.

When I saw him next morning he sat up in his bed and partook of a good breakfast. Consciousness had returned, and all the life functions were in full operation. He died six weeks afterward under symptoms of uræmic intoxication. During these six weeks, up to the hour of his death, he had several other attacks—one very prolonged and almost fatal—during which my son, M. W. Waterman, attended. Artificial respiration was resorted to with the same success.

CASE II.—Mr. E— called upon me during the winter

of 18—, to obtain a death-certificate for a still-born child of seven months' gestation. I expressed a desire to see the child, and promised to visit him during the day. A midwife had assisted during the delivery. It was a cold stormy day and 1 P.M. before I arrived at Mr. E—'s house. He lived in a low basement. Mr. E— was a Hebrew, and according to Hebrew rites, the child had been laid upon a little straw upon the ground, and covered with a light black shawl. It had thus been lying since 5 A.M. As I was examining the child, I could detect some slight twitching movement over the region of the heart. I watched attentively, and I observed the movement again. I had the child removed from the ground and placed upon a pillow on the table. The child was as cold as ice but not rigid. I could detect no heart's-sound, nor any respiratory murmur, but the muscular twitchings were very evident. I immersed the child in a hot bath, and initiated artificial respiration. Twenty minutes passed in this seemingly hopeless work. Then the child opened its eyes. A little more work and respiration began, laborious and interrupted at first, more normal by degrees. The heart's action came up in good style, and a human life was saved! The child thus saved is now one of the most accomplished violinists in this city.

The preceding cases are well calculated to rouse our most serious attention. How often has it been within reach of the physician thus to save life if but strict and critical performance of duty had been attended to! How often are certificates of death written out without first scrutinizing the body, and ascertaining, by all means at our command, whether death has really claimed his victim irrevocably! Mr. B—'s case, especially, offers much encouragement to try revivification in sudden deaths, especially in heart disease. One case thus given back to life and light forms a recollection bright and pleasant upon the thorny path of a physician's life.

103 WEST FORTY-NINTH STREET.

PERMANGANATE OF POTASH IN THE TREATMENT OF AMENORRHOEA.—Drs. Ringer and Murrell have for some time made extensive trial of permanganate of potash as an emmenagogue in those cases of amenorrhœa resulting from some trivial cause, such as getting wet or catching cold. In their experimental observations they gave the one drug only. The most striking results were in young women between the ages of eighteen and twenty-five, who had missed two or three periods. The administration of one or two grains of permanganate of potash in pill, three or four times a day for a few days before the time of the expected period, will bring on the flow almost to a certainty. As a rule, the medicine must be taken three or four days successively to call out the catamenia.

In this connection a letter to the *Lancet*, January 13, 1883, may be of interest. Mr. Martindale writes: "Having during the last few days heard of cases of spontaneous combustion of these pills, which it is very probable will occur if the common excipient containing glycerine, now generally used by dispensers, be used to mass them, I wish to point out that any readily oxidized excipient should not be used. Having prepared a quantity of the pills, I found the following basis to answer best: Vaseline, two parts, paraffin wax, one part; melt, stir till cold, and add kaolin, three parts; mix well. This binds the powdered permanganate together, and with a little dexterity the pills may be rolled out without much difficulty, and dusted over with kaolin. They may be coated with sandarach dissolved in absolute alcohol, and rendered tasteless. Cocoa butter may be used as an excipient, but it in time reduces the permanganate, and it is troublesome to manipulate. In solution a dose of permanganate of potash is very nauseous; in a tasteless pill, which dissolves slowly and yet can be easily disintegrated, it is, besides, more agreeable to the stomach than in solution."

Reports of Hospitals.

THE ANTISEPTIC METHOD IN THE LONDON HOSPITALS.

(As reported by our London Correspondent.)

LONDON, January 22, 1883.

MR. LISTER'S work has now been so thoroughly canvassed before the face of the whole medical world, that it is not unfit at the present time to enquire how far his views and practice have prevailed to influence the hospital surgeons of London in modifying their treatment of wounds, whether the result of accident or caused by operation.

Mr. Lister has for some years been in London, where, at King's College Hospital, he shows almost daily to any that care to take the trouble to follow him round the wards, or to watch him in the theatre, the methods which he advocates, and which are the results of his labors for a very considerable time, as the best for combating the bugbear of "sepsis" which he first and foremost has the credit of showing in its true light, as the cause of those many diseases which formerly wrought such havoc in surgical wounds. To say that he has been successful in demonstrating the value of his theory, conveys but a small idea of the great steps which have been made, owing to the entire or partial acceptance by the surgical world of his views. London is on the whole well provided with hospitals, although their distribution is far from satisfactory, and the appeals for subscriptions which appear every morning in the daily papers show the difficulty which must exist in maintaining, by public benevolence, the funds of all but the happy few which are blessed with rich endowments. Still, as a rule, expense is never spared in rendering all the surroundings of their inmates as favorable to recovery as science can suggest. For this reason, it may be, hospital surgeons in London were well contented with the existing state of things, and were unwilling to allow that any change for the better could be possible from the routine which tradition or their own experience sanctioned. And, no doubt, until Lister's work and its results became known and discussed, they had very fair reasons to be satisfied. Their statistics, when they could be compared with those of other towns, and especially with those of foreign hospitals, were more than creditable. The statistics of the results of operations in some foreign hospitals, at the time when Lister's practice became known and his reasoning appreciated, were truly alarming. It is not to be wondered at, therefore, that foreign surgeons welcomed any method which offered prospects of obtaining better results under the same hygienic conditions; and we need only to look at the results obtained by Volkmann of Halle, under a lack of hygienic precautions which is almost incredible, to understand the enthusiasm with which all the work of Lister has been received abroad.

It will, then, be a matter of no little surprise to your readers to know that it is rare to find among the visitors to Mr. Lister's wards and the followers of his practice, many of the surgeons to London hospitals. Before leaving Edinburgh, statistics were published which contrasted the results obtained by Mr. Spence with those of Mr. Lister under the same roof, and, therefore, the same conditions. These were decidedly in favor of the latter's practice, and should have induced all who had the opportunity to see for themselves by what means such results were brought about. For it is not by reading or by listening to his description of others that a fair idea of the method can be obtained. The details are so carefully carried out, and their importance is so essential to the principle, that it can only be by continuous and careful study that any imitation can be attempted.

So much has already been spoken and written on the subject that it would be out of place in the present article to discuss the many objections to some of these de-

tails, but it may be well just to advert for a moment to the course which is followed with all wounds in Mr. Lister's wards. For example, let us take a simple operation, such as an amputation of the breast. So soon as the patient is under the influence of chloroform—which is still used in preference to ether at King's College Hospital—the parts around are sponged over with a weak solution of carbolic acid, 1 to 40 parts of water. So, too, are the surgeon's and assistants' hands, and the sponges to be used in the operation are dipped in the same solution. When all is ready the spray apparatus, placed at a convenient distance, is brought to play over the part, the patient's face being protected by a towel, and the management of the spray being the sole duty of an assistant. The instruments to be used are all immersed in a solution of 1 in 20 of carbolic acid, and are immediately replaced in it when not in use, the solution being contained in a large flat tray which stands on a small table within reach of the operator, and a towel soaked in the solution is spread just below the breast of the patient, upon which they may temporarily lie in the full atmosphere of the spray. When the diseased part has been removed, the vessels are tied with carbolized catgut, and all bleeding having ceased, a drainage-tube which has been carefully cleansed and washed inside and out with the stronger solution is inserted at the most dependent part, a separate opening in the skin being made, if necessary, to obtain that object. The edges of the wound are then brought together by sutures either of wire or of carbolized silk, and if there be much tendency in the wound to gape, or if the tension be great, the deeper parts are drawn into apposition by two or three stout silver-wire sutures made fast at each end to flat pieces of lead, the edges of which are turned up in such a manner that the wire can be easily secured by a turn or two around them.

On this accurate approximation of the deeper parts of all such wounds great stress is laid, and it is considered essential to secure rapid union of all such cases. The wound is then dressed, a narrow piece of "protective" being laid along the whole of its length, and one or two layers of gauze wrung out in carbolic solution being laid over and freely overlapping it. Above this the gauze dressing is carefully laid, and consists of seven or eight layers of dry gauze, with a piece of mackintosh beneath the outermost layer, and this is secured by a bandage of the same material. In order to ensure the accurate fitting of this dressing, which is sufficiently extensive to cover a wide area around the neighborhood of the wound and to pass up into the axilla of the affected side, an elastic bandage is adjusted so as to bind down the edges in all directions and obviate any chance of the ingress of air or the disturbance of the dressings by the movements of the patient. As soon as all this is completed the spray is withdrawn; but should any accident occur to the spray apparatus during the progress of an operation, a piece of linen soaked in carbolic lotion is always at hand to protect the whole of the wound.

The case is generally dressed on the following day with the same antiseptic precautions, and these are used until the wound is entirely superficial, when they are discarded, and ointments containing boracic acid are substituted. Such is a rough sketch of the method followed by Mr. Lister and those who adopt his treatment in its entirety. But it must not be supposed that any description can give an adequate idea of the precautions which are taken by all concerned in an operation such as that above described to thoroughly guard against the possibility of sepsis. Nothing but careful watching of the author's work can give the full estimate of its thoroughness. Mr. Lister himself attends to the dressing of all his cases whenever it is possible; but he has so thoroughly imbued his house-surgeons and dressers with the details of his system that he can well afford to trust them. So it is that all recent wounds are treated on this principle, whether they be the merest trifles or whether they are

complicated with a fractured bone or an injured joint. In all cases the wound is thoroughly cleansed by syringing into its innermost interstices a solution of carbolic acid, and then dressed in the same way as a wound caused by operation.

It is, perhaps, in the surgery of the joints that the contrast between past and present methods of treatment is most strongly marked. Any one who recollects the gravity with which an accidental wound of the knee-joint was regarded fifteen years ago—and with very good reason, for the tables of our hospitals show how fatal was such an injury—and contrasts with these tables those which have been published in connection with such injuries under the care of Mr. Lister, will be forced to confess, *nolens volens*, that some great secret has been unravelled which has divested this injury of most if not all of its dire fatality. But that is not all. The immunity which attends accidental injuries of joints has increased the number and magnified the nature of the operations which can be performed upon them with an almost entire freedom from those sad and frequent consequences which formerly made surgeons hesitate long before they proposed to the patient an operation, such as the removal of a loose cartilage, which incapacitated him from following any useful pursuit. Contrast with former experience the fact that since 1871 Mr. Lister has treated forty cases of injuries to healthy joints without a death, that these cases were in hospital wards, and that in only one, where the wound was made by the surgeon, did suppuration occur, and we need hardly search for further proof of the advance in surgery which has taken place in consequence of the method which has been so carefully and earnestly established.

As has been said, the number and the nature of operations upon healthy joints has been increased, and we need only look at the list of those which occur in the table to wonder at the boldness or extol the enterprise of a surgeon who dares to unite, by wire, the ends of a fractured patella, and to drain the knee-joint for relief of the effusion consequent, and who obtains after this, as a result, a united patella and a joint in no wise impaired as to its mobility.

It is not our purpose to detail the many operations which can now be performed with comparative safety, but we have thought it worth while to instance a few, in order to show the difficulty which some of the older surgeons must feel in reconciling such bold measures with all the teaching and experience of their earlier days. To this must be attributed, in some measure, the hesitation which in many cases has been shown to welcome or adopt any new method. Still it has been forced upon them to make a very great and thorough change in the treatment of their cases, and it has transpired that although many surgeons would deny that they are followers of Lister in all the details which he considers as vitally necessary to the complete and thorough carrying out of his views, yet they would indignantly repudiate the assertion that they were not "antiseptic" in their treatment of all their cases. Thus it has come about that to distinguish his own practice from that of others who are antiseptic but not Listerian, the author of this change of circumstances speaks of his own work as "aseptic," meaning by this distinction of terms that in his own case a distinct principle is followed which attains the ideal of results, viz.: a complete absence of putrefaction—an asepsis, while under the longer word are comprised "those methods by which the occurrence of putrefaction is more or less interfered with, but all acting on a more or less imperfect principle."

(To be continued.)

IODIDE OF BARIUM.—This substance, which, by the way, is actively poisonous, has been used in France as an application to enlarged lymphatic glands, and more especially as a local application in chronic eczema. For this purpose it can be mixed with a petrolate.

Progress of Medical Science.

THE TREATMENT OF LOBAR PNEUMONIA.—In a clinical lecture on pneumonia recently published in the *Lancet*, Dr. Francis Delafield speaks as follows regarding treatment: The treatment of lobar pneumonia calls for the exercise of much knowledge and judgment on the part of the physician. It is necessary to be practically acquainted with the course of the disease, and to appreciate fully the exact condition of each patient. There is no routine treatment for pneumonia; each case must be managed on its own merits. If we see a patient during the first twelve hours of a pneumonia, the question presents itself as to whether we shall try to abort the disease. This may be done in two ways: by general bloodletting, or by large doses of calomel. The latter plan is the one more frequently employed in New York. From twelve to twenty grains of calomel are placed on the patient's tongue, and this dose may be repeated in six hours. In favorable cases either the bloodletting or the calomel may cause defervescence to take place within a few hours. But both these plans fail in more cases than they succeed. Ordinarily no such attempt is made to abort the disease. Our first care is to put the patient into a condition of absolute rest. He is to be kept in bed, fed on fluid food, and given opium in small doses. Everything which can annoy or irritate the patient is to be strictly avoided. If the temperature runs between 100° and 104° it requires no treatment. If it rises higher than this we may sponge the skin with alcohol and water, give diaphoretics, and aconite or veratrum viride in small doses. Large doses of quinine, cold baths, and cold affusions not only make no permanent reduction in the temperature, but they are positively dangerous. The pulse should regularly be between 100 and 120. If it is above 120 and feeble, we should endeavor to render the heart's action slower and stronger. The most efficient agent for this purpose is alcohol. Either wines, whiskey, or brandy can be prescribed. The amount of alcohol used is to be regulated by its effect on the pulse. It is often well to combine with it either opium or the liquid extract of convallaria. This seems to be the only indication for the use of alcohol in lobar pneumonia. Unless it is required as a cardiac stimulant, the patient is better without it. If the breathing is not only rapid but oppressed at the onset of the disease, the patient may often be relieved by the use of wet cups, dry cups, warm fomentations, or mustard plasters over the whole of the chest. If such oppression continues through the disease, it may be mitigated by the use of calomel and opium in small doses, by aconite and veratrum viride, and by diaphoretics. For the pain in the side, the restlessness, and the sleeplessness, the most efficient remedy is opium, selecting the preparation and the dose to suit each patient.

From what has been said, you will infer that many cases of pneumonia require no treatment but rest and opium; and it is true. If the disease is running a mild and regular course, you are not likely to improve matters by interference. The only indications for treatment are to relieve an abnormal development of any of the symptoms which may threaten to disturb the patient.

ALBUMINURIA AND ANASARCA FROM CONTUSION OF THE KIDNEYS.—M. Boissard, in *La France Médicale*, reports a case of anasarca occurring after contusion of the loins. There was no hæmaturia, the urine was abundant, but contained a large amount of albumen. The anasarca disappeared in eight days, but the albuminuria persisted for a month.

CHANGES OF THE SOLAR AND HYPOGASTRIC PLEXUS IN PERITONITIS AND TYPHOID FEVER.—Dr. Kalantarianz has examined microscopically the condition of the solar and hypogastric plexus in eight cases of peritonitis and five of enteric fever, and found that both in the latter

and in acute cases of the former disease there are constantly present morbid changes in the ganglia, which point to the development of an acute interstitial inflammatory process, with subsequent opaque swelling of the parenchyma of the nerve-cells and their ultimate fatty degeneration, brown pigmentation, and atrophy. In the chronic forms of peritonitis the alterations consisted chiefly (1) in simple and degenerative atrophy of the ganglionic cells, which very often were found entirely disintegrated and transformed into mere accumulations of an amorphous pigmentary matter, and (2) in increase and sclerosis of the ganglionic connective tissue.—*London Medical Record*, January 15, 1883.

THE MEDICAL TREATMENT OF OBSTINATE NEURALGIA.—M. Verneuil, in a communication to the Surgical Society of Paris (*Le Prog. Méd.*, No. 49, 1882), referring to the surgical treatment of obstinate neuralgia, said that all therapeutic resources should be exhausted before surgical interference was undertaken. He recalled a case which was cured by hyoscyamin, after resection of all the ends of nerves and even amputation had failed to give relief.

PARTURITION IN PRIMIPARÆ OF ADVANCED YEARS.—Mangiagalli has advanced the opinion that the difficult labors usually observed in primiparæ of advanced years are due to some physical defect independent of the age of the patient. The women are deformed, and on this account marry late in life; but had they married earlier the same difficulties in parturition would have been encountered. In order to test this theory Dr. Rumpe has examined the records of one hundred primiparæ, over thirty years of age, at the Marburg Clinic. His investigations lead him to reject Mangiagalli's views. He concludes that the difficult child-birth in such cases is due to two causes—sluggish pains and rigidity of the soft parts. Another cause he finds in the relative frequency of male births in these cases. Out of the 100 mothers 8 died. The mortality among the children was also greater than in the first labors of younger women.—*Archiv. für Gynäkologie*, vol. xx., 1882.

HYDATIDIFORM DISEASE OF THE CHORION.—Dr. Stephens writes to the *British Medical Journal*, January 27, 1883, as follows: "On September 7th, I was sent for by a midwife to attend Mrs. C—, who was flooding. On my arrival, the hemorrhage had stopped. On making an examination, the uterine sheath was not sufficiently dilated to be able to ascertain its contents. On passing my hand over the abdomen, I remarked to the midwife how unusually circular it was. On the following afternoon, I was again hastily summoned, and found the woman had lost much blood. On making an examination, I found that, by a little manoeuvring, I could insert my hand into the uterus; and I vividly remember how astonished the midwife and Mrs. C— looked, when I informed them that it contained no child. In fact, the patient stoutly declared that she had felt the child many times; and that, being the mother of thirteen children, all living, she ought not to have been mistaken. After administering a full dose of ergot, some sharp uterine pains followed, soon expelling a mass, which, when collected, filled three ordinary sized chamber-utensils. After this jelly-like mass had been expelled, she made an uninterrupted recovery."

THE TREATMENT OF DYSENTERY.—In the *British Medical Journal*, January 27, 1883, Dr. Rawle describes a plan of treatment of this malady, which has proved very successful in his hands. Having placed the patient between warm blankets, a pint and a half of warm water, at a temperature of 90° F. is injected. This is seldom retained longer than a few minutes, but is pronounced very grateful to the patient. When the water has soothed the mucous membrane of the colon and rectum, and brought away any effete matter, two ounces, by measure, of the following enema is administered with a gum-elastic bottle. R. Quinine sulphate, ten grains; compound tincture of camphor, four drachms; decoctum amyli to

two ounces. Mix, and when about milk-warm, inject, which is generally retained; but, if ejected, it may be repeated after an hour or two. This has been found of great service, and very grateful to the patient. The effect is like magic. If griping pains be felt over the region of the epigastrium, half-drachm doses of chlorodyne, in some aromatic water—mint, caraway, or aniseed—should be given. The diet, of course, should be of the most soothing kind: jellies, isinglass, linseed, toast- and barley-water *ad libitum*. Ipecacuanha appears of little service, and Mr. Rawle has discarded it from his treatment. Warm turpentine stupes on warm flannels, over the hypogastrium prove very beneficial.

RUPTURE OF THE AORTA DURING PARTURITION.—Dr. Heinricus relates the following case: A woman, thirty-eight years of age, of apparently good health, was first seen after labor had begun. The os was dilating, the pains were regular, and everything seemed to be progressing favorably. Half an hour later she was suddenly seized with convulsions and died in collapse. A living child was delivered with the forceps. At the autopsy a rupture of the aorta was discovered, situated about three-fifths of an inch above the semilunar valves. The visceral layer of the pericardium was torn, and the pericardial sack was distended with blood.—*Centralblatt für Gynäkologie*, December 16, 1882.

SIR WILLIAM GULL ON SCIENTIFIC MEDICINE IN GENERAL PRACTICE.—In the course of an address delivered on January 17th, before the Metropolitan Counties Branch of the British Medical Association, on the subject of the "Collective Investigation of Disease," Sir W. Gull, observed: "It will be admitted that, had we leisure, proper means at our disposal, and from previous training a fitness for exact observation, we should find in general practice one of the most valuable fields of pathology, as here and here only we have before us the earliest signs of departure from health, and the only opportunities for tracing the course of a disease from its beginning to its end. Having passed many years in hospital and private practice, I have come to see that experience gained in the latter is necessary for the correction of that acquired in the former, especially as helping toward a truer pathology. It will perhaps, and naturally, be objected, that it is almost impossible to organize for any useful purpose the labors of men already overburdened by the cares and fatigue of practice; and that there is neither time nor fitness for delicate inquiries on their part. Admitting that this objection is valid, it may be urged in reply, that it need not be insuperable. It cannot be denied that when we see the meaning of the apparent trifles which in practice would otherwise oppress and worry us, our burden is thereby much lightened, and that nothing could encourage us more than to feel that even one daily observation recorded was adding to our general store of knowledge, and making the path of practice more easy. There is no tonic to the mind greater than the sense of work done; and our journey is likely to be made shorter, as it certainly will be easier, if the way is illuminated. We, indeed, owe it to those members of our profession, who are admittedly overwhelmed by the apparently senseless details of their work, to promote a movement like collective investigation, the object of which is to establish order out of chaos, and to help them to stamp a scientific value upon facts hitherto only burdensome. If we compare the unflagging interest of any pursuit where the aim is high and clear with the tediousness and wearisomeness felt when working in the dark, we shall readily admit that we are actually lightening the burdens of practice by thus adding to them, and by giving some portion of them a sense and meaning. It is the spirit of a man which enables him to do his work lightly and cheerfully, and he will certainly be helped in this by a combination with fellow-workers on the same subject."—*British Medical Journal*, January 27, 1883.

REGIONAL PHYSIOLOGY OF THE BRAIN.

WHEN we come to the matter of regional physiology, we find ourselves in the midst of problems which still await complete solution, but the painstaking researches, the past eleven years, first of Fritsch and Hitzig, later of Munk, Ferrier, and others have done much toward clearing away the difficulties. The connection of aphasia with definite lesion in the posterior part of the third frontal convolution of the left hemisphere had been determined by Broca, as a result of some hundreds of observations, confirmed by the necropsy; but this first and capital fact in cerebral localizations was little understood and bore little fruit, till Ferrier confirmed conclusions, established by the French physiologist more than forty years before, co-ordinating these conclusions with his own valuable discoveries. That Broca's convolution is, in *right handed* individuals at least, the cortical centre for word ideation and word execution, seems to be a legitimate inference from some thousands of observations now on record. Ferrier's explanation of the occurrence of the speech-centre on the left side—that is, in the early history of the race, communication was by manual signs and gestures before language was invented, and the articulating centres were educated and became the organic seat of volitional acquisitions on the same side as the manual gesticulating centres, and as most people are right-handed, the education of these centres takes place in the left hemisphere—seems both possible and probable.

Lesions of the speech-centre which extend considerably into the antero-frontal lobes have been found to be attended not only with aphasia, but with amnesia—loss of the memory of ideas, as well as loss of words, and verbal expression. Multitudes of well-attested cases on hospital files and in medical journals substantiate this. Other considerations, such as the effect of destruction of these “inexcitable” lobes, go to show that their main function is psychical. If any motor influence emanates from them—and very many of the anterior fibres of the corona radiata certainly terminate in this part of the cortex—such influence would seem to be of an inhibitory character, *i.e.*, restraining, rather than inciting.¹ Ferrier's experiments, and a great number of subsequent experiments by Yeo and others, which confirm this, and the results of lesions of these lobes in

man, seem certainly to give striking support to the ancient and prevalent view (for which phrenology is probably largely answerable), that the frontal lobes have more to do with intellect than any other part of the brain.

It must be confessed that when first the proposition was formally announced that the parietal lobes were principally concerned with motor and not psychical function, it took almost the whole medical world by surprise. *A priori* it seemed quite improbable that “such valuable material as we must needs suppose the gray matter of the convolutions to be, should be taken up in such, so to speak, menial work as bending or straightening a limb” (M. Foster). It must be remembered, however, that the larger part of the lives of the greater portion of the animal kingdom, man not excluded, is taken up with motor performances of a very menial kind, which certainly require but very little intellect for their direction, no more in fact than the antero-frontal region might be supposed capable of supplying, and that *a priori* there can be no improbability in the supposition that a man's limbs and muscular groups have their representative centres in the cerebrum. The phenomenon of descending degeneration of the medullary strands between Ferrier's cortical centres and the basal ganglia, in the case of lesions of the motor area, and the coincidence of this degeneration with similar degradation of the motor columns of the spinal cord, has been noted by Charcot and Flechsig, and seems to point to direct anatomical connection between the anterior and crossed pyramidal columns of the spinal cord and those cortical regions. Moreover, Franck and Pitres have shown, by the results of section of those medullary fibres which terminate in the gray matter bounding the fissure of Rolando, that secondary degenerations occur precisely similar to those which occur in motor spinal nerves after their separation from their trophic centres in the spinal cord, and they reason from this (and it seems to us justly) “that the medullary fibres between the cortical centres and the lower motor nuclei, bear the same relation to the nerve-cells of the cortex as the spinal motor nerves to the multipolar cells of the anterior cornua.”

If electrical stimulation of certain areas of gray matter bounding the fissure of Rolando in the monkey (the crucial sulcus in the dog), have produced definite motor results, so that what will occur under similar circumstances can now be predicted with certainty, destruction of these areas, whether by caustic in the animal or disease in man, produces motor results no less constant and definite. Experimenters working in the same line with Ferrier (Carville and Duret, Luciani and Tambourini, notably Yeo) have, in numerous instances, added confirmation to Ferrier's experiments, and hundreds of careful clinical and post-mortem observations have demonstrated the concomitance of general or limited paralyses with lesions more or less circumscribed of those portions of the parietal lobes now known as Ferrier's motor centres.

Among the important contributions which have from time to time appeared in these columns, and which throw light on certain aspects of this subject, we may signal the papers of Seguin and Dalton, in *THE RECORD* for 1881. Seguin has found the “New Phrenology” (as a popular

¹ We have similar instances of motor neurility which is inhibitory, in the cardiac branches of the par vagum, in the depressor nerve of Cyon, and other vaso-dilator nerves.

scientific journal terms the modern doctrine of localizations) a valuable aid to diagnosis, and says with regard to Ferrier's statement of these localizations, "these are not theoretical guides, they are valuable life laws, and there has not a year passed the last five years that I have not seen cases illustrative of them, and verified them by post-mortem examination." He cites cases, occurring in his experience, where the diagnosis was made with great accuracy. In other instances, recorded by other observers, as Wernicke and Hahn, cortical abscesses have been diagnosed by these rules (motor and sensory [limbs] paralysis occurring in members on the opposite side), the skull has been trephined, the abscess evacuated, and amelioration has followed the operation. In other cases, light has been thrown on certain obscure forms of epilepsy, which have been found to be due to irritative or "discharging lesions" of the motor cortical regions ("Jacksonian epilepsy"). It is worthy of note that Dr. Hughlings Jackson, reasoning from clinical and pathological observations of unilateral and localized epileptiform convulsions, formulated in advance of any experiments of Fritsch and Hitzig views of the etiology of those convulsions, which—at the time considered fanciful—are now found to be in striking accordance with Ferrier's observations, and those of his German predecessors.

The experiments of Dalton (recorded in the paper alluded to) corroborate the position of Ferrier that the angular gyrus is the seat of visual perception. In two cases in which he excised the angular convolution in dogs, blindness of the opposite eye followed. These results coincide with those of Ferrier on monkeys and McKendrick on pigeons, but await confirmation by a sufficient number of pathological observations in man.

With regard to the other sensory centres, there is still great uncertainty; Munk, Luciani, and Tambourini agree with Ferrier in admitting the existence of such centres (as of hearing, smell, taste, tactile sensibility), but differ as to the precise location. Ogle, however, and Hughlings Jackson relate cases confirmatory of the location of smell and taste in the lower part of the temporo-sphenoidal lobe.

Whether or no the occipital lobes (which like the antero-frontal are inexcitable) have any loftier function than that of ministering to the visceral sensations, being the cerebral centre of the appetite for food, or whether they have even this humble function, is still undetermined. Considering the great account which, in man as well as in other animals, is made of the gratification of the alimentary propensities, it would seem *à priori* probable that the stomach has its representative in the cerebrum.

We propose at a future time to take up other aspects of the subject of localizations.

TRACING CONTAGION.

THE following analytical observations of Professor J. Leidy may assist the practitioner to trace the cause of anthrax or splenic fever, when other causes of contagion are not apparent.

A number of cases in the same herd, owned by a farmer at Salem, N. J., having died very suddenly, the veterinary surgeon submitted a specimen of the blood

from the last victim to Professor Leidy for microscopical examination.

The animal was apparently well on one evening, and was milked as usual; it died the next morning. The cause was not clear, but was suspected to be the result of anthrax or splenic fever. A post-mortem examination was made the following day; and the abdominal viscera were found much congested, especially the spleen, which was gorged with blood. The specimen of blood from the spleen was examined and found to be teeming with bacteria of the form known as *Bacillus anthrax*, which is now viewed by most competent authorities as the cause of anthrax. The bacilli were actually more numerous than the blood-corpuscles, which appeared unchanged.

This case shows that milk is forwarded to market drawn from cows which are within a few hours of their death from splenic fever. Such milk can hardly be wholesome, and doubtless contains the bacilli capable of giving contagion.

Let us hope that the fat from the carcass of such animals is not sent to the nearest oleomargarine manufactory, as this substance is rendered only at a temperature under 120°, by the patent which is now supreme. We need not state that the thermal death-point of bacilli is far above such a temperature, and we leave our readers to draw their own conclusions respecting the results when such uncooked animal produce is used as an article of diet.

ÆSTHETICS AND DRUG-TAKING.

It is a matter of some practical interest to the physician that he take account of the results of the impact of the æsthetic wave upon the medical profession. It has long been observed that, with developing civilization, the people have become more intellectual, and the doctor has had in consequence to become more wide-awake. The education of the æsthetic sense in this country has been more recent, but it too is now a thrifty and vigorous cultus. Our modern society, in fact, has become much more sensitive to what is disagreeable and much more responsive to what is agreeable than was formerly the case. The beautiful is ardently admired and the ugly as warmly detested. Æsthetics even supplants morals with many, especially of the fairer sex, vulgarity being often thought worse than wickedness, and good manners quite an atonement for bad morals.

Now, if any one doubts the bearing of all this upon medicine, let him prescribe nauseous draughts and ill-smelling mixtures among his upper-class patients for a while. He will soon find that it does not answer. The young physician of to-day has an additional lesson to learn. He must not only give the right thing therapeutically, but must give it agreeably.

The pharmacist has become well aware of this new demand of the public—the tradesman being always most plastic to developmental readjustments or fashion's changes. Note the history of cod-liver oil. No scientific problem has received more attention or diverted more cerebral force than has that of making oleum morrhue palatable. Even though it has proved a kind of North Pole of pharmaceutical ambition, the struggle is not yet given up. The demand for agreeable medicines

shows itself also in the remarkable growth of the pill trade. The bolus is now hardly known, and we give in small and slippery pellets what our grandfathers conquered asphyxia in attempting to swallow. The pill, to be sure, is tasteless, and its æsthetic value is chiefly negative, yet it accomplishes the object of attacking the disease without afflicting the senses. There are also popular practitioners in our city who are not content with this merely negative position of the pill, but require their druggist to put upon it a seductive coating of gold or silver foil. The mental effect of taking these expensive-looking globules is not to be ignored.

The manufacture of elixirs, syrups, and various aromatic compounds has also vastly increased under this demand for the non-offensive in medicine. To make something which "children will cry for" is the honest ambition of many a druggist who appreciates the signs of the times. Since medicine-taking with Americans often becomes as much a pastime as a serious business, the syrup and elixir trade flourishes, greatly to the delectation of childhood and the content of the adult.

The moral to be drawn from the state of things thus portrayed is most apparent and important. The practitioner must regard not only the disease but the palate of his patient. Not that we would always recommend the prescription of pleasant-flavored mixtures. There are some persons who measure the value of their medicine by the strangulating effects which accompany its taking. But the wise physician will study the whole case, and in prescribing for the disease not forget the individual.

MEDICAL EXAMINATIONS IN ENGLAND.

THE English Government, as previously noted, proposes to introduce a measure, during the present session of Parliament, for the purpose of amending the law relating to the licensing of medical practitioners. The recommendations of the late Royal Commission will probably be adopted, and a single board will doubtless be constituted before which the medical student will be sure of obtaining a fair examination in every branch of his art. We believe also that a second and higher board will be constituted, with power to confer degrees and higher titles.

The *Lancet* states that the present condition of the licensing system admits of no other course, and that students, the profession, and the public demand such a change. This state of things hardly accords with the generally received opinion that the English system of admitting medical students to practice is in advance of our method. Our medical brethren on the other side appear to consider that their system is far from perfection. We shall watch with interest this attempt to form an independent and competent board of examiners for medical students in England, and trust that the reform may produce a system which may be accepted as a model for some improvement in the same direction here. Medical opinion in this country is being gradually educated to the point of considering that State examinations for the degree of Doctor of Medicine are the main means of establishing an absolute, consistent, and trustworthy standard of medical requirements. In fact, all measures for reforms in medical education must necessarily centre around this point.

LIMITING THE POWER TO CONFER MEDICAL DEGREES IN MASSACHUSETTS.

A MASSACHUSETTS Judge recently decided that the Bellevue Medical College of Massachusetts was legally incorporated, and could legally confer degrees in medicine, even upon persons who had not studied medicine the proper length of time. Thereupon several new institutions started up, and the business of diploma-making in Massachusetts on the Buchanan plan seemed to be in a most prosperous condition. The legal profession has, however, stepped in, and on February 24th the Attorney-General of the State rendered an opinion, in which he held that institutions of learning or science created under the general law do not possess the power of conferring degrees.

This takes away the powers of the medical diploma mills, theoretically. It remains to be seen whether they will actually be stopped in their operations.

In this connection we would refer to the fact that somebody calling himself a "student" has asked the *Kansas City (Mo.) Times*: "Is there any State in the Union where I can practise medicine without a diploma? I have attended one course of lectures." To which the *Times* replied: "Yes—in Massachusetts."

JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION.

THE Board of Trustees appointed by the American Medical Association to decide upon the plan of a weekly medical journal has issued a circular requesting medical periodicals to inform the profession that sufficient encouragement has been received from different quarters to warrant a report to the next meeting of the Association in favor of the establishment of said journal. We think the committee is in error in issuing a circular of this kind, which does not give the figures upon which such conclusions have been based.

As we understand it, this proposition involves very considerable financial responsibility somewhere, with no slight possibility of greater or less deficiency, to be made good, we suppose, by the Association. If this be so, it is right that the members should have the same data as that possessed by journal committees, that each member may exercise his own judgment before voting upon so important a matter. Let the committee give a synopsis of the pledges it has received from the forty thousand copies of the programme it has sent out. Let it state the estimates of the cost of publishing the journal received from four principal cities, etc. To give these figures only at the time of the meeting in June next will not afford the members of the Association a fair opportunity for considering them. Let us have light now.

THE POLLUTED WATER-SUPPLY OF BOSTON.

THE subject of water-supply in Boston is one that at present interests the inhabitants of that city very much. For the past two or three years, ever since the new basins connected with the Sudbury River have been used as a source of supply, the water has been bad—very bad. Experts pronounce it the worst water, with perhaps one exception, furnished to any city in the country. Those of the citizens that can afford to buy spring water at the rate of ten cents a gallon—as much as the farmers

in the centre of the State get for their milk—do so, and grumble at the expense added to the high water-rates. Dr. Bowditch echoed public sentiment when he said that the Boston water was not fit to drink, and was sometimes too dirty to bathe in.

For some time past the Water Board has endeavored to protest against the public voice in this matter, and has insisted that the water was good, though perhaps a little discolored. At last comes an official report from the commission appointed by the City Council, in which the public complaints are acknowledged to have a good foundation, and remedies for the existing evils are suggested.

The chief causes of pollution are, first, the sewage of the town of Natick, which flows directly into Lake Cochituate, and, second, the state of the Sudbury River basins. These basins are nothing more nor less than meadow and swamp lands which have been overflowed without having been at all cleaned, and in many places the water is very shallow, the bottom being made up of the above-mentioned mud and swamp which was lately covered with vegetation, now decaying and being furnished to water-takers in the form of a weak decoction. In such water algae flourish, and by their decay add more organic matter and the very disagreeable fishy taste so much complained of. The remedies suggested are, first, stopping the flow of sewage into the lake, and, second, the removal of the mud and loam from the basins, especially in their more shallow portions. It is hoped that these improvements will take place soon, as the health of the city is seriously threatened as long as the present condition of things exists.

News of the Week.

THE OHIO FLOOD AND TYPHOID FEVER.—Typhoid fever has appeared in the inundated districts of the Ohio Valley.

POISONING OF LUNATIC ASYLUM INMATES.—Eight inmates of the Western Lunatic Asylum at Staunton, Va., were poisoned last week, presumably by some crank having the freedom of the house. Six of the victims have died and two have recovered. The poison, the nature of which is as yet unknown, is supposed to have been mixed with medicines on their way from the dispensary to the wards.

EMERGENCY LECTURES TO LADIES.—A series of "emergency lectures" to ladies is being given by various members of the profession in Boston, the proceeds to be used in aid of the Training School for Nurses. The subjects to be treated of are dressing of wounds, hemorrhage, care of the sick, etc.

A CINCINNATI SANITARY COMMISSION.—The citizens of Cincinnati are urging the passage of a bill appointing a street and sanitary commission for two years, with \$1,000,000 to spend.

VICTIMS OF TRICHINOSIS.—Five members of a family in Port Jervis, N. Y., recently became affected with trichinosis, through eating raw pork. One of the persons, a child, died.

FURTHER BEQUESTS TO OUR CITY HOSPITALS.—The late E. D. Morgan left \$50,000 to the Presbyterian Hospital, and a similar sum to the Hospital for Ruptured and Crippled. The Manhattan Eye, Ear and Throat Hospital was also liberally remembered.

SMALL-POX IN COLORADO.—Notwithstanding the strenuous efforts to throttle it, the small-pox appears to be getting the upper hand of the authorities. The Leadville public schools have been closed. A new pest-house is being built there. The alarm is becoming general and is reaching out into the surrounding towns, some of which are establishing a quarantine.

DR. M. T. COUNCILMAN has been appointed the pathologist to the Baltimore Academy of Medicine.

A NAVAL MEDICAL SOCIETY.—We are glad to learn that the medical staff of the Navy has organized a Society called "The Naval Medical Society," in order to establish more intimate social and friendly relations among its members, to furnish occasions for the interchange of professional experiences, and to assist each other in scientific inquiry and research. Every officer of the medical corps has the right of membership upon notifying the Secretary that such is his desire.

The Society is to have regular meetings on the first Thursday of every month, in the city of Washington, and at such other times as the business committee may consider advisable, or when five other members may so request.

LIVELY MEDICAL WORK.—The investigation recently undertaken regarding the condition of Sing Sing Prison, reveals a bad state of affairs. The prison physician testified that there was really no wholesome air in the prison when occupied, and that the cells were all badly ventilated.

The same physician testified that he had 30,000 visits from convicts in the year 1881, and 29,000 in 1882. His daily visits amounted to from 80 to 100, and all of these were disposed of in about two hours. This really appears like the application of the lightning calculus to medicine. In our city dispensaries, where no time is wasted on individual patients, it is rare for more than 20 or 30 patients, at the utmost, to be disposed of in two hours. The doctor makes a most reasonable request when he asks for two assistants.

Notwithstanding the defects above alluded to, we are told that the mortality rate is less than at any other prison in the country except one in Wisconsin.

THE NEXT MEETING OF THE AMERICAN PUBLIC HEALTH ASSOCIATION.—At the meeting of the Executive Committee of the American Public Health Association, held in Washington on the 16th ult., the date of the next meeting of the Association was fixed for November 13th to 16th, inclusive, at Detroit, Mich. The meeting was not so fully attended as was expected, Drs. Lindsley, Conn, Speed, and Frazier being absent.

An informal discussion of the programme was had, but its scope was not definitely settled upon, the details being left with Dr. Ezra M. Hunt, President of the Association. The subjects: Vital Statistics and Modes of Registration; Adulteration of Food and Legislation Thereon; Etiology of Malaria; the Physics of Hygiene;

House Drainage, and kindred topics, were the more important matters discussed.

It is understood that the next volume of the "Transactions" (vol. viii.) will be ready for delivery within six months, and that it is to be published on much more favorable terms than any former volume, thus greatly reducing the price.

THE APPROPRIATION FOR THE LIBRARY of the Surgeon-General's Office, U. S. A., including the Museum, has not yet passed the Senate. When it came up in the House Committee it was reduced from \$10,000 to \$5,000, but the original amount was restored when the Legislative bill was put upon its passage. The Senate Committee having it in charge has cut it down again one-half, but its friends anticipate no trouble in getting the full amount restored in the Senate.

An appropriation covering the fifth volume of the Index Catalogue of the Library of the Surgeon-General's Office will go through without opposition. The fourth volume is about one-half completed, finishing the letter "E," and running through "Fevers."

There is no bill before Congress this session looking to the transfer of the Surgeon-General's Library to Congress; in fact, Congress has no building suitable for its own Library as yet, the bill for the same having failed to get a two-thirds vote under suspension of the rules on Monday last.

THE NATIONAL BOARD OF HEALTH'S BILL has failed to come up in the House, and the \$10,000 recommended by the sub-committee for "pay of members" was struck out of the Sundry Civil Appropriation bill, thus leaving the Board with no appropriation whatever. The only health legislation proposed by this Congress is the following, taken from the Sundry Civil bill:

"The President of the United States is hereby authorized, in case of a threatened or actual epidemic, to use a sum, not exceeding \$100,000, out of any money in the Treasury not otherwise appropriated, in aid of State and local boards, or otherwise, in his discretion, in preventing and suppressing the spread of the same and maintaining quarantine at points of danger."

It also appropriates \$50,000 in aid of State and municipal authorities and corporations engaged in transportation of neat cattle, in establishing regulations for the safe conveyance of such cattle and shipment thereof, so as to prevent their exposure to pleuro-pneumonia, to prevent the spread of said disease and to establish quarantine stations; and to provide proper shelter for neat cattle imported.

A DIRECTORY FOR TRAINED NURSES.—The process of searching for a nurse has hitherto been a tedious one, and full of annoying delays. Hours of valuable time are spent in going from house to house with a selected list of names, finding again and again that nurses have moved, or are with cases, or are not at home. A systematic registry of nurses avoids all this delay and trouble, and we are glad to learn that the managers of the Bellevue Training School have recently established such a registry of the graduates of that institution at their office, No. 426 East Twenty-sixth Street. Here the addresses of the nurses are kept and their engagements known, and the superintendent can also answer all

questions as to the special qualifications of each nurse. In this way all necessary information can be obtained at once by simply applying at the Training School, and a nurse engaged without waste of time.

THE BLACK SOAP IN KERN'S CATAPLASMATA.—Numerous correspondents who have answered the query in a previous issue agree in saying that the black soap used in connection with Kern's cataplasmata is but another synonym of the ordinary *sapo viridis* of our Pharmacopœia.

HOSPITAL SUNDAY DISTRIBUTION.—The Hospital Saturday and Sunday Fund Committee have agreed upon the ratio of distribution of the sums collected through the various channels employed by the association. The report of the committee shows that the total amount of designated and undesignated funds collected was \$33,762.72, and this amount, minus \$3,935.56, was distributed among the following institutions:

St. Luke's Hospital.....	\$7,674 04
Hospital for Ruptured and Crippled.....	405 00
Mount Sinai Hospital.....	4,200 00
German Hospital.....	3,255 00
Presbyterian Hospital.....	4,191 03
St. Mary's Hospital.....	2,052 01
House of Rest for Consumptives.....	1,420 00
House of Holy Comforter.....	1,228 75
Home for Incurables.....	956 71
New York Eye and Ear Infirmary.....	217 60
New York Infirmary for Women and Children.....	561 00
New York Ophthalmic Hospital.....	570 00
Hahnemann Hospital.....	946 02
French Hospital.....	595 00
Orthopedic Hospital.....	570 00
Ophthalmic and Aural Institute.....	550 00
Manhattan Eye and Ear Hospital.....	475 00

Total.....\$29,827 16

SENSELESS OBJECTION TO TRANSFUSION.—Mr. Henry Bergh, in a recent issue of the *Evening Post*, comments savagely upon an article by Dr. Joseph W. Howe, which appeared in THE RECORD of February 3d. The letter of Mr. Bergh is intemperate and full of misstatements. So far as it implies that the transfusion of blood is not a useful practice, and one which has already saved many lives, it should receive a prompt answer and refutation. For the rest, Mr. Bergh's passions and prejudices are too apparent to mislead any but the very ignorant.

LEADING OFF.—The Annual Commencement exercises of the Buffalo Medical College were held February 27th. Diplomas were conferred on fifty-six graduates.

PROVIDING FOR IMMIGRANTS.—The bill introduced by Senator Miller, of New York, to amend the Act of August 3, 1882, regulating immigration, has not yet found its way to the surface, though it was read twice and referred to the Committee on Commerce in January last. It provides for a tax on all immigrants of fifty cents a head, creating a fund for the purpose of defraying the expense of regulating immigration, etc.

THE NATIONAL MEDICAL COLLEGE of the Columbian University held its Annual Commencement exercises on March 2d.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, January 24, 1883.

GEO. F. SHRADY, M.D., PRESIDENT, IN THE CHAIR.

(Continued from p. 218.)

DR. LEWIS SMITH presented specimens of

ACUTE TUBERCULOSIS IN THE LUNGS OF CHILDREN.

DR. BEVERLEY ROBINSON presented a specimen of

ANEURISM OF THE AORTA,

accompanied by the following history, furnished by Dr. Devlin, senior physician to St. Luke's Hospital: Mary E—, thirty-two years of age, married, and a native of the United States, had an attack of rheumatism eighteen years ago, which involved the ankles, and continued in a chronic form for about two years; a certain amount of synovitis remained permanently. The patient stated that for a number of years she had had oedema of the feet at intervals of one or two months and following slight exposure to cold. She had suffered from slight dyspnoea for several years, but there had been neither palpitation nor cough. Urine normal. About three years ago, after exposure, she had a chill, followed by fever and pain in the left mammary region. Sputum scanty, but color not noticed. The fever and dyspnoea increased, and the patient had two distinct chills, each accompanied by an increase of pain in the left side of the chest. During the last four days dyspnoea has been very marked. Cough incessant, and the patient has become very weak. Temperature, 101° F.; pulse, 140. The specific gravity of the urine was 1.018; otherwise normal. No cardiac murmur was detected; the heart action was very rapid and weak. There was diminished respiratory murmur over the left lung anteriorly and posteriorly. Subcrepitant râles were heard over both lungs. There was marked stridor and tracheal râles. A few hours afterward the breathing became very labored and the patient became cyanotic. An emetic of ipecac gave considerable relief. Harsh sonorous ronchi were heard over the whole chest posteriorly. Laryngoscopic examination was negative. On the following day her breathing was very labored, an emetic was administered, and the patient was cupped over the chest with marked relief. On the following day the patient became comatose and died.

At the autopsy the left ventricle of the heart was found hypertrophied, and the valves normal. The muscular tissue was pale, yellowish, and contained considerable fat. The aorta was slightly atheromatous throughout.

There was an aneurism two and one-half inches in diameter opposite the second and third dorsal vertebrae which were slightly eroded. The sac was lined with laminated fibrin and communicated with the aorta by an irregularly circular, smooth-edged opening, half an inch in diameter, situated at the junction of the descending portion of the arch with the thoracic aorta. The kidneys were small and granular, the cortex was thin, the markings were obscure, but the capsule was not adherent. The lungs were congested and cedematous, and in the lower lobe of the left were small areas of recent consolidation.

Dr. Robinson also presented a specimen of

RETRO-PERITONEAL SARCOMA,

accompanied by the following history, furnished by Dr. Devlin, Senior Physician to St. Luke's Hospital: Christopher L. H—, thirty-eight years of age; native of the United States; single; clerk by occupation; was admitted to the hospital November 19, 1882. His family and personal history were negative. Six weeks ago, while quietly walking across the room, he was suddenly seized with violent pain in the left hypochondrium. It

was so severe as to cause faintness and profuse perspiration, lasted about half an hour, and then subsided to some extent, but had been constant ever since, although there had been no paroxysmal attacks. The pain did not radiate into the pelvis. There was no pain or difficulty in micturition, and there was no change in the appearance or quantity of the urine. During the last two weeks the patient had had several attacks of vomiting, but no hematemesis. Fifteen days ago for the first, and on several occasions since, the patient had found in the urine blood-clots about half an inch in diameter, and varying in length up to two inches. Two weeks ago, and also one week ago, he had an attack of severe precordial pain and dyspnoea. Bowels have been constipated throughout the entire sickness. The urine has gradually become high-colored, but remains clear. There has been marked loss in flesh and strength. Examination of the urine reveals specific gravity of 1.030, acid, no albumen, and on microscopical examination blood-corpuscles, but neither renal epithelium nor casts. Liver and spleen not enlarged. There is a tumor in the epigastric region extending one and a half inches below the umbilicus, three inches to the left, and only slightly to the right. Its free border is separated by a slight sulcus from the left lobe of the liver. The tumor has a convex margin directed toward the left side, and a depression resembling the hilus of the kidney toward the median line.

November 24th.—Left epididymus enlarged and contained nodules. The patient has never noticed the enlargement before, but has had a slight dragging sensation in that region for a few days.

November 25th.—The patient was examined by Drs. Alonzo Clark, Packard, A. H. Smith, Leaming, Wheelock, and Ball. No positive diagnosis was reached. Dr. Clark believed that the tumor did not involve the kidney, but probably was malignant. Dr. A. H. Smith believed that it was a displaced kidney, and was the seat of tubercles or cancerous infiltration.

November 26th.—The patient passed a blood-clot one-twelfth of an inch in diameter and three-fourths of an inch in length.

December 3d.—The patient vomited matter containing clots of blood. Examination by the house surgeon per rectum and with the sound introduced into the bladder determined that the prostate was normal. He also examined the lungs and found no evidence of pulmonary disease.

On December 7th the tumor was aspirated by Dr. Ball, and a small quantity of bloody serum was obtained, which, on microscopical examination, showed only red blood-corpuscles and granular matter. The patient was examined by Dr. Weir, who diagnosed post-peritoneal neoplasm, and the diagnosis was concurred in by Dr. W. T. Bull.

December 8th.—The patient vomited blood copiously during the night. The feces had a tarry appearance. Rectal alimentation.

December 9th.—Vomiting of blood continues at intervals. Distressing hiccup has developed, which is relieved only by chloroform.

December 11th.—The patient begins to retain food by the mouth.

December 13th.—Hiccup severe and vomiting frequent.

December 15th.—Patient ate a hearty breakfast of eggs, fish, and bread, and it was retained. Begins to complain of painful micturition, and passes about forty ounces of urine daily. Slight cough with hæmoptysis has appeared.

December 27th.—No change in the physical signs in the chest. There has been occasional hæmoptysis.

Patient died on December 28th with the ordinary symptoms of oedema pulmonalis and heart failure.

At the autopsy two ounces of dark fluid blood were found in the pelvic cavity. A round mass of the size of a cocoanut was firmly attached to the vertebral column

posteriorly, occupied the left lumbar region, and to it the adjoining loops of intestine and other organs were firmly adherent. It was situated in front of the descending colon.

The spleen was large and soft, and contained no secondary deposits.

The liver contained about ten secondary nodules, most of which projected somewhat above the surface, and varied in size from a cherry-pit to a hen's egg. On cross section these nodules presented a mottled appearance, due to excessive vascularity and recent hemorrhage. They were quite soft and friable, were not surrounded by a well-marked capsule, but there was neither diffuse infiltration nor inflammatory zone. The other portions of the liver were pale and apparently fatty.

The left kidney was united by loose adhesions to the principal tumor and its ureter was, for several inches, firmly attached to the growth. The pelvis was dilated considerably. The right kidney contained one secondary deposit about the size of a pin's head. A nodule of the new growth, about the size of a bean, was found in the small intestine. Both lungs were studded with nodules of various sizes, the largest being of the size of an English walnut. There were bronchitis and œdema. There was a nodule of new growth in the left testicle. All the other organs were essentially normal.

Cross sections of the tumor presented the ordinary gross appearance of a very vascular sarcoma. At several points hemorrhage had occurred within the neoplasm.

Microscopical examination.—The tumor and the secondary deposits in the lungs and the liver are the same in their microscopical structure. The tumor is chiefly composed of cells and blood-channels which vary in size and shape. Some cells are large and irregular in their outline, some are spindle-shaped, and many of them are ovoidal. They are all furnished with one or more nuclei.

These cells are closely bound together by a minimum amount of inter-cellular substance, and arranged to form cavities, which are irregular in shape and differ in size, and contain blood and fibrin. The blood in these cavities is in contact with the cells already described. Everywhere throughout the tumor there are large areas of fibrin surrounding blood-channels, which in places communicate with each other. There are a few cells in the meshes of the fibrin which are large and spindle-shaped.

The tumor is not surrounded by a capsule. *Diagnosis*—Sarcoma.

DR. JANEWAY had seen two cases of lympho-sarcoma near the kidney. In one the growth occupied the position of the kidney exactly, and the kidney, completely normal, was situated within its capsule.

REPORT OF THE COMMITTEE ON MICROSCOPY.

DR. BIRDSALL presented the following:

The Microscopical Committee beg leave to report that the tumor of the uterus of a seal presented by Dr. Liautard, at the second meeting in December, was found to be a myo-fibroma, in which the muscular elements largely predominated, and were bound together with the connective tissue forming irregularly concentric layers and whorl-like arrangements, constituting a tumor of very firm consistency. A very scanty vascular supply existed. In the centre of the growth a spot, 2 to 3 cm. in diameter, was found, in which a fatty and granular degeneration had commenced.

The Society then went into executive session.

SOLUBLE SALTS OF CAFFEINE.—The double salts, salicylate of sodium and caffeine and benzoate of sodium and caffeine, are very soluble and can be used for hypodermic injections. Citric acid does not form a definite salt with caffeine, but simply augments its very slight solubility in water. The citrate so commonly used, therefore, is really quite insoluble.—*New Remedies*, February, 1883.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, February 26, 1883.

DAVID WEBSTER, M.D., PRESIDENT, IN THE CHAIR.

DR. CHARLES HEITZMAN read a paper entitled

THE INTIMATE NATURE OF TUBERCULOSIS; ITS TRANSMISSIBILITY AND ITS PARASITIC ORIGIN.

When in 1873, the author of the paper first announced the reticular structure of so-called "protoplasm," he stood alone; since that time, however, a large number of good observers have corroborated the fact, and E. Klein, in 1878, enumerated over a dozen who, with more or less variations, and slight differences in their views, agree that "protoplasm" is really possessed of a reticular structure. Some of these have seen the structure in living and moving elements; some have claimed priority for its discovery in different tissues and parts of the body; e.g., for liver-epithelia, although the reader distinctly stated in 1873 that all epithelia have the reticular structure. In 1880, S. Stricker described the reticular, or trabecular structure in saliva-corpuscles, and he saw the trabeculae in motion so long as the corpuscle itself remained alive. Thus the last doubt was removed that the trabeculae themselves are the living matter proper. In the same year, S. Stricker stated that the basis-substance of the cornea may, under favorable conditions, under our very eyes, be transformed into "protoplasm." Quite recently, end of 1882, he asserted, in a public college lecture, that he is now thoroughly convinced of the correctness of the reader's statement, made in 1873, that the basis-substance is endowed with properties of life, the same as the cornea-corpuscles themselves, and added that it took him six years' labor to convince himself of this fact, which abolishes the theory: "Omnis cellula, ex cellula." Thus the speaker, at present, finds his two main assertions corroborated by the best microscopist abroad, and may, with some right, expect that also the third assertion, as to constitutional differences in the amount of living matter present in different elements of the same individual will, in time not far distant, meet with the approval of good observers.

On the ground of the new views, the process of inflammation becomes easily understood, for nothing is required, but a liquefaction of the basis-substance in any variety of connective tissue, in order to set free the living matter previously buried therein, with the result of the reappearance of the medullary elements which in the earlier stages of development share in the formation of the basis-substance. From any portion of the living matter of these newly developed corpuscles, may the new formation of elements ensue, leading to what is known by the term "inflammatory infiltration." So long as these corpuscles remain inter-connected, the inflammation remains plastic or formative, leading eventually to hyperplasia of the invaded tissue. As soon, however, as the newly formed elements are torn asunder, the inflammation assumes the character of destruction or suppuration.

In every inflammatory process a number of capillary blood-vessels are destroyed by being directly transformed into inflammatory corpuscles. Should the inflammation remain formative, new blood-vessels originate in the newly formed tissue; while in suppuration the blood-vessels are destroyed permanently. Any individual of good constitution, i.e., supplied with a sufficient amount of living matter will, in the process of plastic inflammation, reform the lost blood-vessels; while in persons of a poor constitution, i.e., those who have comparatively little living matter in their bodies, in any inflammatory process the reformation of the lost blood-vessels may be wanting, the product of inflammation in such persons must, by lack of nutrition, shrivel, dry out, as it were, and thus a product results known as tubercle. Tubercle,

therefore, is a product of inflammation destitute of blood-vessels; it makes no difference whether the process runs a slow course in the form known as chronic tuberculosis or phthisis, or an acute course, such as in miliary tuberculosis. Scrofulosis and tuberculosis from this point of view are pathologically identical, though clinically different, manifestations of a general, constitutional trouble, namely, want of living matter in the organism.

Several years ago the reader drew attention to the fact that the amount of living matter may directly be observed under the microscope in single pus or colorless blood-corpuscles. In persons of an excellent constitution these corpuscles look nearly homogeneous, viz., are richly supplied with living matter, and do not exhibit a reticular structure. The coarser the reticulum, respectively, its points of intersection, the surer it is that the corpuscles come from an individual with good constitution; the finer, on the contrary, the reticulum, the more delicate its points of intersection, the more are we entitled to define the constitution of the person, who furnished the corpuscles, as a poor or tuberculous one. Thus we are enabled to determine the constitution of any person by simply examining his pus or colorless blood-corpuscles. All products of tuberculosis and scrofulosis are known to be composed of elements scantily supplied with living matter, therefore finely granular, and here again is a proof of the fact that tuberculosis and scrofulosis are strictly constitutional diseases.

As to the transmissibility of tuberculosis, neither the observations of the physicians, nor the experiments of the pathologists since Villemin, have yielded positive results. Herbivorous animals, especially rabbits and guinea-pigs, may be rendered tuberculous by almost any injury. Much rarer is this the case with carnivorous animals. Not only the sputa of tuberculous persons, but almost anything brought under the skin of animals, for instance, pieces of gutta-percha, paper-scrap, etc., nay, injected granular aniline colors will produce tuberculosis in rabbits, especially in guinea-pigs, if these animals are kept imprisoned in cellars and poorly fed. A few days' sojourn in cellars is sufficient to produce diarrhoea in these animals, and a rapid sinking of their constitution, which, by itself, is poor. No rabbit, on the contrary, can be rendered tuberculous by any injury, or contamination with sputa of tuberculous persons, or any other material, if kept in yards, in freedom, and allowed to have plenty of fresh air and proper food. All experiments have, so far, proved that the infection of animals is successful only if the constitution be a poor or "tuberculous" one, and impaired by improper sanitary conditions. The experiments made on rabbits by transferring the so-called "tuberculous virus" into the anterior chamber of the eyeball, with subsequent tuberculous "deposits" in the iris, were the apparently most striking ones. Recently, however, the secretions of syphilitic ulcers or vegetations were transferred into the anterior chamber of the named animals, and the result was identical with that of experiments made with the "tuberculous virus," viz., tuberculous iritis.

Koch deserves great credit for his brilliant discovery of the bacillus in tubercle-matter and in the sputa of tuberculous persons. As to the presence of this low organism in the sputa there can be no doubt; it is plainly seen in specimens treated with certain aniline dyes (mainly gentianin and fuchsin). Recent researches made in Berlin and Vienna scarcely leave a doubt as to the diagnostic and prognostic value of this bacillus; for it is found only in persons invaded by tuberculosis, and the greater its number the more rapid is the course taken by the disease. But the proof that this bacillus causes the disease, stands, so far, only on the experiments of Koch himself, known to be an accurate and conscientious worker. If, by inoculation of the bacillus, gained by pure culture, tuberculosis can be brought about in rabbits, guinea-pigs, and rats, will this prove anything in the face of the fact that these animals, under the above-named

conditions, have been rendered tuberculous by inoculation of a great many other substances, partly or entirely neutral? The bacillus, whose germs may circulate in the liquids of any persons, may find a favorable soil for development in products of inflammation, deprived of their blood-vessels, in so-called cheesy masses, in the same manner as bacteria develop in the depth of the tissues—for instance, in the medulla of bone in osteo-myelitis without being in a direct causal connection with the primary inflammatory disease.

The paper being before the Society, the President invited DR. W. T. BELFIELD to open the discussion, who thought that Dr. Heitzman laid too much stress upon the fact that tuberculosis can be produced by simply introducing a mechanical irritant under the skin, etc. He then reviewed some of the points connected with this part of the subject, as already presented in a lecture delivered before the Alumni Association [the lecture will appear in a subsequent number of this journal], and again expressed the opinion that tuberculosis is infectious, as pyæmia is infectious. The real question, however, is not whether tuberculosis is infectious, but, What is the agent in that infection?

DR. A. JACOBI doubted, from a clinical standpoint, the absolute accuracy of some of the claims which Dr. Heitzman regarded as established facts. That the microscopical appearances of miliary tubercle and tubercular infiltration were identical, particularly when their centres were examined, had been well known for some time. But the origin of the two conditions which seemed so much alike must be different. Else, why does the miliary tubercle develop most commonly in very young infants, while the tuberculous infiltration is seen by far the most frequently—many cases occurring to be sure between the ages of five and ten years—between the ages of fifteen and twenty-five years? There must be some reason for this clinical fact. Concerning the peculiar condition found by microscopical examination of the white blood-corpuscles, Dr. Jacobi thought that the view had a certain amount of support in the irregular appearances presented by the milk globules, and yet he believed that the conclusions reached from such examinations must be restricted to the present condition of the individual, and not be applied to the general constitution. Dr. Jacobi believed that tuberculosis can be transmitted, and also that diseases regarded as the least transmissible can be transmitted, as, for example, eczema. Eczema may be transmitted from the head to a lower extremity by means of the finger nails, and the diseased particles produce the disease on the part to which they are so transmitted because the tissues of the person are in such a condition that an inflammation of this kind is readily produced. To say that the disease under these circumstances is of constitutional origin, does not explain the phenomenon. Thus he believed that phthisis was probably transmissible; transmissible when there exists either a congenital predisposition or a lowered state of the system already referred to.

DR. HEITZMAN was very much surprised to hear Dr. Belfield speak of pyæmia as an infectious disease, and thought that he must undoubtedly have used the word for septicæmia. Pyæmia certainly is a non-infectious disease, while septicæmia, as is well known, is infectious. With reference to the transmissibility of eczema, mentioned by Dr. Jacobi, he thought the argument did not prove very much. The fact that an eczema existed under the knee, and the next day upon the face, did not prove that the affection is contagious. The fact could be best explained on the ground that the skin is a continuous organ, and when diseased in one part of the body, it may, by reflex action, become affected in other parts of the body.

The Society then adjourned.

A HOMŒOPATHIC HOSPITAL is to be established in Minneapolis, Minn.

NEW YORK ACADEMY OF SCIENCES.

Stated Meeting, January 22, 1883.

PROFESSOR NEWBERRY, PRESIDENT, IN THE CHAIR.

MR. EDWARD PAYSON THWING, of Brooklyn, read a paper entitled

TRANCE IN ITS RELATION TO SEA-SICKNESS.

The histories of nine cases were given in which, by artificially inducing the hypnotic or trance condition, sea-sickness was allayed.

CASE I.—An English lady, aged fifty, of spare habit yet naturally vigorous constitution. She came on board an Atlantic steamer in ill-health, and sea-sickness began soon after. When first seen, two days out of port, she was unable to keep anything on the stomach and had not been able to retain any food since coming on board. Taking his position behind her, as she was extended in a steamer-chair, the speaker simply used gentle but firm pressure on either side of the head, following this with quiet and slow movements of the hands across the eyes and along the course of the orbicular muscle of either eyelid, uttering assuring words meanwhile. Little, if any somnolence followed, but, within a moment, the patient exclaimed "What a *heaven* it is to be relieved from pain!" An hour later she ate a dinner of her own selection, of which roast mutton and caper sauce made the central figure.

CASES II. AND III.—Two professional men on the same ship, similarly affected and similarly treated. With one of them drowsiness at once was induced and encouraged. No complaint of sea-sickness was afterward heard from them during the voyage.

CASE IV.—Two weeks later, between Stavanger and Trondhjem, on the west coast of Norway, a hearty, stalwart English sportsman complained of nausea, vertigo, and the other sensations of sea-sickness. He became drowsy as soon as manipulations about the head began. The slumber was made so profound that a sharp puncture of the hand caused no wincing. When the words "All right!" were spoken he waked and found his illness gone. He complained no more.

CASES V. AND VI.—A German governess and her pupil were crossing with me from Dover to Calais. The younger was vomiting violently and the teacher was on the point of following her example. Both were relieved by being thrown into the trance state.

CASE VII., like No. V., was that of lucid trance, without slumber. The vomiting was arrested and quietude was so suddenly established that an attendant suspected chloroform, and asked with earnestness, "What did you put on your hand?"

CASE IX.—Here hysteria, neuralgia, and sea-sickness made a joint assault on the patient, a middle-aged lady, in mid-ocean. A steady gaze full in the eye secured a concentration of thought and expectation, which the voice is sometimes sufficient to secure. The trance was almost immediate, and became so profound that some little force, thrice repeated, was needed to rouse. The sensation was described as that of delicious excitation at the beginning, which was followed by dreamless repose, of which no recollection was had.

Other cases had occurred in the speaker's experience, but did not materially differ in character or treatment.

Mr. Thwing's conclusions were:

First.—That the trance state, so called, will, in many cases, arrest sea-sickness by restoring the nervous equilibrium. Not every one responds, *i.e.*, believes, expects. Not every operator is able to excite expectancy in a willing mind, still less in a reluctant, incredulous mind. Failures are often our best teachers. Those whom I have failed to benefit are generally those who, by attending to or joining in conversation, or by some other diverting circumstances failed to fix their thought on the subject, and those querulous, despairing creatures who

seem determined not to get better, but "enjoy" poor health at home and abroad. Furthermore, failures at the first or second interviews I have found to be by no means decisive or final, as recent experiments with surgical patients have proved. When sequestration and silence can be secured success is sooner gained.

Second.—In transform states, where control is incomplete and unconsciousness is partial, great relief is often had.

Third.—The sense of subjugation and helplessness felt in sea-sickness is an important accessory to the process. It is analogous to that consenting attitude which the lower animals instinctively take when under the hand of the tamer or trainer, and something like the trance of fear, called panic.

Fourth.—The feeling of certainty on the part of the operator is helpful, if not absolutely essential, in awakening expectancy on the part of the patient. This assurance is not shown by bluster, but by gentleness; by undemonstrative rather than by pretentious and dramatic action; by low tones of voice that betray neither hesitation nor doubt; and by the general air of one who speaks a personal, private, and authoritative command. *Possunt quia posse videntur.* Hardly anything is more contagious than confidence or more masterful in power.

A CASE OF TRANCE ANÆSTHESIA.

DR. WILLIAM C. JARVIS presented to the Academy a patient from whose right nostril he had removed the turbinated tissue and re-established respiration after a year's closure, the operation, on January 20th, being performed while the patient was made as perfectly insensible, by Mr. Thwing, as if under chloroform. Other cases were mentioned by him, notably one where the terrified patient had required three attendants to hold her on a previous occasion, but who, under trance-anæsthesia, allowed the introduction and use of the *écraseur* in the removal of a glandular tumor behind the palate, contiguous to the base of the brain.

PROF. NEWBERRY, of Columbia College, remarked that this was a wholesome influence and worthy the attention paid to it. He had seen it utilized in surgery twenty-five years ago. Not all respond, yet in many cases it proves to be a beneficent power. Taken out of the hands of charlatans, it is now being used by those competent to investigate its phenomena.

EXPULSION OF FOUR HUNDRED AND FORTY-ONE LUMBRICOID WORMS WITHIN THIRTY-FOUR DAYS.—Dr. A. C. Pole, of Baltimore, reports (*Medical Chronicle*) the case of a girl aged seven, who had been complaining for months of nausea and colicky pains in the abdomen. The skin was icteric, appetite variable, bowels costive. She was treated for worms and was given *santonin*, *chenopodium*, etc. Within thirty-four days four hundred and forty-one lumbricoid worms were passed, in "lots" varying from one to thirty-five. Dr. Pole says: "Larger numbers than these have been reported, but such a number in so short a space of time I believe to be infrequent. Ransom, in his article on intestinal worms, says that cases are recorded in which various numbers, from one hundred to twenty-five hundred, have been expelled from one person within a few months. Cruvelhier cites a case of an idiot in whose intestines one thousand were found. Dr. Condie has known as many as a hundred and twenty to be voided in a single day by a child five years old. Dr. Meigs says: 'I have never myself known more than six, eight, or ten to be expelled within a few days' time, and very generally there have not been more than three, four, or five.' Hensch states that he remembers a case in which whole vesselsful of round worms were passed for a number of days in succession. Bartholow says there may be one, two, or three worms, or they may reach five hundred or a thousand."

Correspondence.

OUR PARIS LETTER.

(From our Special Correspondent.)

THE TYPHOID EPIDEMIC IN PARIS—DISCUSSION ON THE TREATMENT OF TYPHOID FEVER BEFORE THE ACADEMY OF MEDICINE—THE COLD BATH NOT IN MUCH FAVOR—QUININE AS AN ANTI-PYRETIC—THE BEST MANNER OF USING THE DRUG TO OBTAIN ITS PERMANENT EFFECTS—ALCOHOL AS AN ARRESTER OF TISSUE METAMORPHOSIS—DR. HENRI NACHTEL ON THE PREVENTION OF STREET ACCIDENTS.

PARIS, FRANCE, February 9, 1883.

THE medical journals in and out of France have been so full of the typhoid epidemic in Paris, and the subject has been so ably treated of in your editorial of January 6th, that it would seem unnecessary to say anything more about it; but the importance of the subject having been revived by a remarkable communication made by Professor Germain Sée, at the Academy of Medicine, last week on the therapeutics of this dire affection, will be my apology for reverting to it here.

In reviewing the most recent methods of treatment employed, Professor Sée divided them into three classes, with the view of facilitating discussion. The first, which used to be termed simple expectation, is now decorated with the affix "armed," or, as Dr. Dujardin Beaumetz would have it, "expectation armée." The second has the pretention to be a specific method, that is to say, it has the power of destroying the germ which is the cause of the malady. The third comprises those agents, medicinal or otherwise, which simply reduce the temperature of the body ("antithermiques") and those which attack the fever itself ("antipyretiques"), or perhaps the learned Professor would mean to say, the source or cause of the fever or heat in the body. Professor Sée is not in favor of the expectant method, which he says consists in leaving the cure of the malady to the efforts of nature (*natura medicatrix*), as he had tried this method armed or unarmed, at the commencement of the present epidemic, and the results were anything but encouraging. He has also shown that the so-called antiseptic methods have up till now given no result, in short, they cannot do so in the proper sense of the term, as none of them can reach the seat where the microbe is evolved, even should there be such a thing as a specific microbe.

Before referring to the methods of treatment which he preferred, Professor Sée made a few remarks on the treatment of typhoid fever by cold baths, which he condemned not only as being useless, but absolutely dangerous in this affection, as cases have been recorded of severe and even fatal results having followed the use of the cold bath. The method of the cold bath is, like the other methods, founded on preconceived theories. In the present case the cold bath is employed ostensibly with the view of reducing the temperature of the body, but M. Sée proves that the cold bath has the opposite effect, and he has found that the internal heat is increased, and so is also the process of combustion, hence the necessity for feeding the patients who are submitted to this treatment copiously; but M. Sée has calculated that to repair the enormous waste of the tissues it would be necessary to give the patient at least thirty-five hundred grammes (a little over three pounds) of beefsteak a day, or its equivalent in another form, and it is well known that the digestion of typhoid patients is nil, or nearly so.

From Professor Sée's own experience he has come to the conclusion that the refrigerating property of cold baths is only apparent, or at any rate its effects are not permanent, nor does it shorten the duration of the disease, and if it does not reduce the rate of mortality, the Professor pertinently asks what utility there would be in subjecting typhoid patients to such a barbarous treat-

ment. To fulfil the indications for which cold baths are employed, Professor Sée prefers the use of quinine sulphate and alcohol, which he administers separately or combined, according to circumstances. The former he looks upon as the type of an antipyretic remedy. It prevents the too rapid oxidation of the tissues of the body, and acts on the heart and blood-vessels in the most favorable manner. The sulphate of quinine is also eminently "antithermic." It possesses this property in a much higher degree when given to patients who are suffering from fever than to healthy individuals. The lowering of the temperature of the body is proportional to its previous rise; in some cases, it has even been observed to exceed one degree. The quantity he administers is 2 grammes 20 centigrammes, or about 34 grains per diem, half of which is given in the morning and the other half in the evening, which he never exceeds, as it then becomes toxic. Moreover, he prefers this mode of administering the medicine to small divided doses in the twenty-four hours, as when thus administered it is rapidly eliminated from the system, and its effects are lost. Alcohol is another remedy Professor Sée considers most useful in the treatment of typhoid fever. Far from increasing the temperature of the body, as has been supposed, it does not burn, it prevents denutrition, and thus lowers the general temperature of the patient. In fine, alcohol is a substance that retards the waste of the tissues and prevents emaciation, hence termed "*un médicament d'épargne*." When one drinks spirits one is led to suppose that the temperature of the body is increased, as it produces a sensation of heat, but this phenomenon is merely temporary and coincides with a real diminution of the heat of the body. This effect, however, is less marked than in the administration of quinine. The Professor deems that the combination of the two substances named would be found most useful in the treatment of typhoid fever, or in any other condition where their effects are indicated. In any case, Professor Sée considers them absolutely inoffensive, provided they are employed in the proper therapeutic doses.

Professor Jaccoud, another eminent physician, following in the same wake, made a very interesting communication at the last meeting of the Academy on the same subject. He advocated, with slight modification, the treatment adopted by Professor Sée in typhoid fever, and, like the latter, condemned the cold baths as employed for some time in Germany and now adopted in a general way in Lyons, observing that he has obtained the necessary degree of refrigeration by sponging the body frequently with aromatic vinegar and water, which is attended with much less inconvenience and danger to the patient. He also severely criticised the growing tendency in the profession to adopt the germ theory of disease, and concluded his remarks by the following practical advice: "Whatever may be the fate reserved to microbes it must not be forgotten that we cannot reach or affect them in any way but through the medium of the patient infested with them, and that the power of resistance in the subject should always be kept in view."

Dr. Henri Nachtel, so well known in connection with the Night Medical Service, established in New York, and his efforts to introduce the American system of ambulance in Paris, is now occupied in endeavoring to introduce the system of "street-helpers" as it exists in London, New York, and St. Petersburg, where the policemen have strict orders to afford every help in their power to enable foot-passengers to cross the streets by stopping the carriages which follow in such rapid succession, particularly at certain hours of the day, and where the traffic is so great that crossing over from one side of the street to the other is simply impossible without being run over or knocked down. Dr. Nachtel has had a personal interview with the Prefect of Police on the subject, who has promised to make the necessary arrangements for the carrying out of such a desirable and philanthropic object.

OUR LONDON LETTER.

(From our Special Correspondent.)

MEDICAL ADVERTISING — TYPHOID FEVER — THE COLD BATH, AND OTHER TREATMENTS AT THE LONDON, NORTH EASTERN, VICTORIA, ST. MARY'S, AND UNIVERSITY COLLEGE HOSPITALS.

LONDON, February 13, 1883.

MEDICAL advertising continues to call forth anathemas from the powers that be. The London College of Physicians has on several occasions, by the votes of its fellows, publicly protested against the custom of advertising medical works in lay journals. By an unfortunate coincidence, however, many of the fellows who attend and vote at these meetings at which the resolutions condemnatory of advertising in the lay press are carried *nem. con.* are themselves actually guilty of the offence they condemn in others. In some cases, no doubt, they would say the advertisements are inserted by their publishers. Still the fact remains. A great deal of the agitation has arisen simply from professional jealousy. Those who have attained success and are reaping its rewards would gladly keep them to themselves. The medical journals decry the lay press, because they want to get the advertisements for their own columns. Not many years ago, though, when *The Lancet* was animadverting on this subject, and denouncing some physicians by name, it was pointed out by its contemporaries that *The Lancet* had its contents advertised weekly in *The Times*, large bills of contents exhibited at the Metropolitan Railway stations, and was itself exposed for sale on the railway bookstalls.

Typhoid fever is still prevalent. The cold-bath treatment has made considerable progress in England of late years. Still it cannot be said that we can show results as favorable as those of Liebermeister and other German physicians.

At the London Hospital the cold-water treatment is in use by several of the physicians. In some cases the immersion bath is employed at a temperature of about 60° F. (*i.e.*, ordinary tap water), the patient being placed in this for five or ten minutes. Cold sponging is, however, more frequently resorted to on account of the much less trouble it involves. The patient is directed to be sponged with cold water (or spirit and water sometimes) whenever the temperature is very high. The effect has been tried of placing patients in a bath and pouring over them water from a watering-pot with a hose attached. Drs. Fenwick and Sansom have tried the effect of placing a bed-cradle over the patient so as to raise the bedclothes from off him and within the hollow space thus formed, placing a piece of ice in a saucer so as to cool the atmosphere immediately surrounding the patient. Last year Dr. Sansom employed Rothe's method of treatment in some cases, the notes of which appeared in *THE MEDICAL RECORD*.

At the North Eastern Hospital Dr. Sansom, the senior physician, employs the cold bath treatment extensively. Whenever patients are hyperpyretic they are immersed for a few minutes in a bath containing cold water as drawn from the cistern, and therefore at about the temperature of the air. This is repeated as often as necessary, *i.e.*, whenever the temperature rises again. In severe cases Dr. Sansom has repeated them at intervals of two hours. Dr. Sansom states that he gave quinine an extensive trial some years ago and is not convinced of its efficacy, although he has made use of large doses, *i.e.*, as much as five grains or more to a child of two years. He has also frequently employed the sulphocarbates in cases of typhoid fever. His present treatment, in addition to the use of the cold baths, is mainly dietetic and expectant. A refrigerant mixture containing liquor ammonia acetatis is usually given.

At the Victoria Hospital for Sick Children typhoid fever cases are not admitted. Those originating among patients already in the hospital are placed on a diet of milk and lime-water. Complications are treated as they

arise. For hemorrhage from the bowels Dr. Venu administers an injection of gallic, and opium is occasionally given.

At St. Mary's Hospital the treatment is mainly expectant and dietetic. Patients are fed chiefly on meat broth and milk. Diarrhoea, if excessive, is treated by sulphuric acid and opium. A bed, the upper half of which can be raised or lowered by means of a lever, so as to place the patient at any angle without fatigue to himself, is usually reserved for typhoid cases. The cold bath treatment has not been employed to any extent, but has occasionally been used in hyperpyretic cases.

At University College Hospital the antipyretic treatment is employed both by Dr. Wilson Fox and by Dr. Ringer with good results in many cases.

THE LATE DR. GEORGE M. BEARD.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Will you allow me to say a word in justice to the memory of the late Dr. Beard? I have looked through numerous medical journals and have failed to find anywhere a just recognition of his work and character. Furthermore, I have not been able to find that a single medical society has paid even the conventional tribute of resolutions to his memory. In many prominent medical journals half a dozen lines have been deemed a sufficient obituary. To those who knew Dr. Beard's many contributions to science, his active, keen, and original mind, his tireless industry, and his charming personal character, this seems a shameful neglect.

Dr. Beard, in connection with Dr. Rockwell, was one of the pioneers in electro-therapeutics in this country. Together they gave to the profession general electrization, a therapeutic measure whose value is everywhere acknowledged. Dr. Beard first gave to the profession also definite views and facts regarding neurasthenia; he was the first to study and show clearly and positively that Americans possess a peculiar and peculiarly great nervousness—a fact which, when recently commented upon by Mr. Spencer, in nearly Dr. Beard's language, was received as something wonderful, novel, and true.

Dr. Beard first explained the phenomena of mind-reading; he made original researches in trance and its allied conditions. In the same connection he formulated the sources of error in experimentation and in weighing human evidence. He was a friend of higher education in medicine, and an early promoter of the success of the American Academy of Medicine. He was identified with the reform movement in psychiatry now going on in this country. Aside from these and numerous minor contributions to medicine and psychology, he was a man of attractive character, incapable of double-dealing, true to his friends, helpful to younger men, generous, and of an unvarying good humor under the worst attacks of his critics or his enemies. With the faults only of a too prolific writer, but with the merits of an original thinker, a brilliant worker, and a persistently active scientific investigator, it seems that, so far, but scant justice has been done to his memory.

Very respectfully yours,

SUCCINATE OF IRON IN BILIARY COLIC.—Dr. Jas. A. Stewart, of Baltimore, revives the claim that the hydrated succinate of the peroxide of iron is efficient in the treatment of gall-stones. He reports one case in which a patient, a lady of forty, who had suffered for three months and was greatly emaciated, recovered health rapidly under drachm doses of the succinate. There had been no trouble for two years. Dr. Stewart's case, as reported in the *Maryland Medical Journal*, is not very convincing, as the trouble had only lasted a comparatively short time, and no gall-stones were actually found.

New Instruments.

A NEW INSTRUMENT FOR TESTING THE FIELD OF VISION.

By J. B. EMERSON, M.D.,

INSTRUCTOR IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL; ASSISTANT SURGEON TO THE MANHATTAN EYE AND EAR HOSPITAL.

The principles on which this perimeter is constructed are chiefly the same as those of others now in use.

The arc is a semicircle of five inches radius, perforated at the middle, and divided on its convex surface into eighteen equal parts, and numbered from the middle to the extremities. On each arm of the arc is a perforated slide, so made that small pieces of paper can represent the objective point; and in testing the color zones, colored paper can be used. This slide is held in any position by means of a spring. The support of this arc is a rectangular rod, surmounted by a quadrant. This rod moves vertically in a sheath, so as to be elevated or depressed at will. The perforated axis of the semicircular arc is attached to the upper end of the quadrant, so as to revolve about a horizontal axis. The scale on which the angle of revolution is measured is fixed to the quadrant, and a pointer on the revolving arc indicates the meridian tested. The chin-rest is double, the right for the left eye and *vice versa*. The movement of the chin-rest is also vertical, parallel to that of the aperture, and at a horizontal distance six inches in front of it. The base is loaded. The minimum height is twenty inches, with an extension of four inches. It is made of polished brass, and its weight is about six pounds. The eye of the person tested should be five inches from the aperture, and on the same level with it. This can readily be effected by observing the eye of the person tested through the aperture. In other respects the working of the instrument is similar to that of other perimeters. The advantages claimed for the instrument are:

First.—By means of the aperture the eye of the person tested can be watched, and any deviation immediately detected.

Second.—The double chin-rest brings the eye of the person tested directly in front of the aperture.

Third.—The bearings of the instrument are principally rectangular, so that it cannot "wobble."

Fourth.—The centre of gravity of the chin-rest is directly over the base, while that of the arc is nearly so, thus rendering the instrument little liable to accident.

Fifth.—It is light, portable, and an ornament to the office, rather than a nuisance.

Sixth.—It can be easily and quickly used.

Army News.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from February 17, 1883, to February 24, 1883.

CLEARY, PETER J. A., Captain and Assistant Surgeon. Granted leave of absence for four months on account of sickness, to take effect January 3, 1883, in extension of his authorized absence on certificates of disability. S. O. No. 40, par. 6, A. G. O., February 16, 1883.

HEIZMANN, CHAS. L., Captain and Assistant Surgeon. To be relieved from duty in the Department of the Columbia. S. O. 12, Department of Columbia, February 8, 1883.

TESSON, LOUIS S., Captain and Assistant Surgeon. To be relieved from duty at Fort Clark, Texas, and assigned to duty at Fort Ringgold, Texas, as Port Surgeon. S. O. 20, par. 5, Department of Texas, February 21, 1883.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Comparative statement of cases of contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending February 24, 1883:

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
February 17, 1883.....	0	2	85	7	75	51	0	0
February 24, 1883.....	0	11	86	4	81	44	1	0

SOME CLINICAL INDICATIONS FOR CONVALLARIA MAJALIS.—Dr. E. L. Trudeau, of Saranac Lake, N. Y., writes: "From what has already been published in regard to convallaria, it seems that, as the study of this drug is in its infancy, little is known as yet in regard to the class of patients to whom it is most serviceable. It has been noted that in some cases of cardiac difficulty it acts most energetically, while in others it is of little value. Some broad indications to guide us in its use are, therefore, most desirable. From a year's experience in prescribing this drug, it has seemed to me that such an indication may, perhaps, be found in the fact that it is most successful in all cases where, to restore the balance of the circulation, stimulation of the RIGHT heart is imperative, while it is much less active where increased energy on the part of the left ventricle is called for. Its striking power in controlling dyspnoea in cases of emphysema, fibrous, and chronic phthisis (cases in which digitalis frequently fails), in relieving the orthopnoea of mitral disease, increasing at the same time the flow of urine, and its failure to mitigate the symptoms of aortic mischief or to increase the flow of urine in such cases, are clinical facts which tend to confirm this suggestion. It is in relieving dyspnoea that convallaria attains its most brilliant results, while it has only an uncertain and trifling power over cedema and dropsy, and it succeeds often in precisely the cases in which digitalis fails. Another indication for its use not hitherto dwelt upon, is in controlling the symptoms of purely functional heart disorder. Its efficacy in such cases confirms Dr. Beverley Robinson's opinion that it acts through the nervous system. Paroxysmal palpitation and dyspnoea due to nervous causes, rapid and irregular heart-action dependent upon debility, are symptoms almost always benefited by it, and which often entirely

disappear during its exhibition. Convallaria is a drug which offers a most promising field to physiological research, and it is to be hoped that extensive experiments upon animals will, before long, clear up many doubtful points in regard to the proper indications for its use."

THE DOSE OF CONVALLARIA.—Dr. H. L. Taylor wishes us to state that the largest dose of convallaria used by him was one drachm, and not one ounce, as stated by one of our correspondents in a recent issue of THE RECORD.

DR. HARVEY L. BYRD'S ARTICLE.—Dr. Byrd writes: "Please have the following corrections made in my article of February 17th in the next issue of THE RECORD, viz.: in line 26, on page 178, second column, read, 'Caucasian and negro races when it is found breeding *inter se*,' instead of '*intense*.' In the tenth line from the bottom, same page and column, insert *of* after the word descendant. The word *penal*, in line 18, first column, page 179, should read *plural*."

THE TREATMENT OF PNEUMONIA.—We are indebted to Dr. W. Thornton Parker, Acting Assistant-Surgeon, United States Army, Fort Elliot, Texas, for the following item, communicated to him in a private letter by Professor Baumler, of the University of Freiburg, Baden: "Our treatment in cases of pneumonia in the Freiburg Hospital is chiefly directed toward sustaining the strength of the patient until in the natural course of the disease the pyrexia leaves him. As the pyrexia is one of the chief causes of the exhaustion which in severe cases gradually sets in, we try to keep down the body-heat by means of cool baths or wet packing, as well as by quinine (fifteen to twenty grains in one dose in the evening) or salicylate of soda (sixty to eighty grains within an hour in the middle of the night). The patient must be sufficiently fed by broths, beef-tea, and milk, and in every case we give from one-half to one pint of light wine, to which the populace is accustomed, in the twenty-four hours. *An ice-bag is applied to the chest when there are pleuritic pains.* Dover's powder or morphia is only given when there is restlessness or great pain, or diarrhoea. With very sharp pains in the side we apply the morphia hypodermically. If there be much bronchial catarrh accompanying the pneumonia, we give ipecacuanhæ in infusion with or without opiates. Sweet spirits of nitre I have never employed in pneumonia. Altogether, it is but very seldom used in Germany."

MENSTRUATING AT THE AGE OF SEVENTY-SIX.—Dr. W. S. Higgins, of Penfield, Ill., sends us the history of the following singular case: "Mrs. Eliza McG—, born in Harrison County, Ky., September 28, 1806; worked on a farm, doing a great deal of out-door work; began to mature at the age of fourteen, but did not menstruate until at the age of eighteen; from fourteen to eighteen suffered more or less with wandering pains, supposed that washing clothes in the river was the cause of the suppression. Married at the age of twenty, first child born at the age of twenty-one. Enjoyed usual good health. Had twelve children, last one born at the age of forty-six. For seven years after the last child was born menstruation irregular and very copious. Since then *very regular* (with good health) *until the present time, at the age of seventy-six*, and always preceded with same kind of bad feeling that ushered in the flow when young."

THE HISTORY OF QUARANTINE AT PENSACOLA.—In 1853 yellow fever was brought to the navy yard by the St. Vixen from the West Indies and spread to the military post at Barancas, between which places there was unrestricted intercourse. In 1863 it was introduced into the navy yard by the United States supply vessel Nightingale, and although there were three thousand troops at Barancas, not a case occurred there, owing to a "strict quarantine of cavalry pickets" which was placed around the military camp. In 1867 it was brought to Pensacola

by ship and spread thence to the navy yard through constant intercourse between the two places. A picket line established against both these places prevented its reaching Barancas a second time. In 1874 it was again brought by ship to Pensacola and thence through intercourse to the navy yard; Barancas again quarantined against the two places and escaped the third time. In 1875 it was brought to Barancas by the Von Moltke; Pensacola and the navy yard quarantined against Barancas and both escaped. The past year the navy yard and the towns of Milton and Millview established rigid quarantine against Pensacola and all escaped, while other towns and hamlets which did not quarantine were attacked by the disease and suffered severely.

THE CHILDREN OF WOMEN SUFFRAGISTS.—In a list recently given of the children of twelve leading woman suffragists, it was shown that there was a remarkable preponderance of daughters. Among the forty-three children thirty-two were girls.

CARBONATE OF POTASH IN DIPHTHERIA.—Dr. S. S. Cartwright, of Roxbury, N. Y., sends us the history of two cases of diphtheria with croup occurring in the same family. The first patient, a boy of three years, died after a brief illness. About two weeks later, the second case, that of a boy four years old, developed. The disease went on rapidly and unfavorably, showing much the same bad symptoms as at first. Emetics were used, and chlorate of potassium given. Some improvement took place on the fourth day, but severe and apparently fatal relapse occurred five days after. Two grains of potass. carbonat. were then administered every hour, when improvement soon appeared, and the child recovered. Dr. Cartwright ascribes much virtue to the potass. carb., which, he writes, is recommended by Vogel. Our correspondent appears to have ignored local treatment, the use of alcohol, and of muriate of iron.

PRIMARY CANCER OF THE PANCREAS.—Dr. Chas. G. Partridge, of Bellows' Falls, Vt., sends us some facts regarding a case of primary cancer of the pancreas involving that organ alone. The case occurred in the practice of Dr. E. S. Albee. The patient was a woman only twenty years old. She had been ill "from an unknown cause for about seven years." The diagnosis of the disease was made from a microscopic examination of the tumor by Dr. White. The case is somewhat unique, and pathologists will be apt to doubt the diagnosis until the facts are more fully presented.

THE MEDICAL REGISTRATION LAW IN PENNSYLVANIA.—Dr. F. Griswold, of Sharon, Mercer County, Pa., relates, in the *Medical and Surgical Reporter*, cases illustrating the successful action of the registration law in his county.

NEW YORK MEDICAL JOURNALS.—Nine general and seven special medical journals are published in this city. There are four weeklies, seven quarterlies, four monthlies, and one bi-monthly.

THE SECOND GERMAN CONGRESS FOR INTERNAL MEDICINE meets at Wiesbaden, April 17 to 20, 1883.

THE TREATMENT OF CHILBLAIN.—*New Remedies* publishes a list of thirty-seven different remedies for chilblain, taken in part from the *Chemist and Druggist*. The list includes all kinds of liniments and ointments, also hot water, electricity, balsams, acids, and that odoriferous panacea, iodoform. Yet we are unable to say which is the specific.

SYRUP IODO-PHENIQUE (DÉCLAT).—The composition of this preparation is as follows, according to *New Remedies*: Iodine, five one-thousandths to one part; phenic, or carbolic acid, one to five parts; water, or other suitable solvent—say a solution of iodide of potassium containing one-tenth to two parts of the salt—enough to make one hundred parts.

ON THE RELATIONS OF MICRO-ORGANISMS TO DISEASE.

THE CARTWRIGHT LECTURES, DELIVERED BEFORE THE
ALUMNI ASSOCIATION OF THE COLLEGE OF PHYSICIANS
AND SURGEONS, NEW YORK.

By WILLIAM T. BELFIELD, M.D.,

LECTURER ON PATHOLOGY, AND ON GENITO-URINARY DISEASES (POST-GRADUATE
COURSE), RUSH MEDICAL COLLEGE, CHICAGO.

LECTURE III.

IN 1879 Neisser made the assertion, based upon numerous examinations, that there is present in the purulent discharge of gonorrhœa, whether from urethra, vagina, or conjunctiva, a micrococcus not found in other pus, distinguished by its size, shape, and mode of reproduction. Neisser's previous work entitled this assertion to respectful consideration, and it was at once subjected to extensive tests. The reports have been, with one exception, unanimous in corroborating Neisser's assertion in all its details. I may mention especially Ehrlich, a most expert and experienced, yet conservative and trustworthy observer; Gaffky, a pupil and present assistant of Koch; Aufrecht, of Magdeburg; Löffler, Leistikow, Bockhart, Krause; and among the ophthalmologists, Leber, Sattler, and Hirschberg. The only dissenter, so far as I know, is Dr. Sternberg, who asserts that this micrococcus form is widely distributed, and is, in fact, the same as that which Pasteur has shown to cause fermentation of urea.

Several attempts have been made to inoculate human subjects—since animals are not susceptible to the contagion—with the isolated micrococci. Bokai, in Pesth, asserts the induction of urethral gonorrhœa in three out of six students so inoculated; but as he neglected to keep them in solitary confinement during the trial, the experiment is not so convincing as it might be. Bockhart, having cultivated the organisms on gelatine, inoculated with the fourth culture a paralytic hospital patient, and observed a typical gonorrhœa on the sixth day. Sternberg cultivated micrococci from gonorrhœal pus in flasks, and observed only negative results in each of five patients inoculated therewith. Thus far, therefore, it is not decisively established that the bacterium associated with gonorrhœa is the cause of the disease. Dr. Sternberg's present experiments, like all his previous work, evince great care, skill, and a sincere desire for truth that cannot be too much admired; yet his deductions would be far more convincing if he would substitute a solid for the liquid culture medium.

Sattler has recently found micrococci, apparently identical with those of gonorrhœa, in the conjunctival granulations, and affirms that inoculation with the organisms, isolated by cultivation, induced the disease in a human subject.

Micrococci, then, exist in the human body, locally and generally; yet excepting gonorrhœa there is no decisive evidence that a specific micrococcus is associated exclusively with any one specific morbid process in the human subject. But I would again remind you that many of these organisms are individually so minute that absolute, and hence comparative, measurements cannot be as yet

accurately made; further, that micrococci morphologically identical may be physiologically distinct. Hence it cannot be asserted at present that the same species is present in septicæmia, pyæmia, etc., although the contrary is not yet established beyond doubt.

Turning to the other tribes of bacteria, however, we find more definite information; for in size, shape, mode of propagation, often of locomotion also, they present such differences that a distinction into species is often possible.

The disease variously designated anthrax, splenic fever, malignant pustule, woolsorter's disease, charbon, and by the Germans Milzbrand, is proven to be not only associated with, but also caused by, a bacillus. About this all controversy has ceased; inoculation with the bacilli, isolated by filtration, flask cultures, by cultures upon solids, by scores of observers, have always and invariably given the same result; Koch has even induced the disease by inoculation with the one hundred and fifteenth successive culture upon solids. Further experimentation is as unnecessary as further proof that a dog can be poisoned with strychnine. Anthrax is as yet the only disease proven to be due to a bacterium, by demonstrations so clear and unequivocal as to convince skepticism and silence sophistry. It is, therefore, the rock of ages on which the bacteriologists seek refuge from the waves of ridicule; the cross to which they cling amid the storms of adverse criticism; the strong castle from which they repel the impotent assaults of their enemies. The knowledge of certain facts as to the occurrence of this disease has extreme value for those of us who, having no prejudices nor views to protect, belonging to no camp nor sect in pathology, are actuated by a desire, not to demolish every one whose views do not accord with ours, but to ascertain and interpret intelligently all facts bearing upon the relations of bacteria to disease.

Anthrax is endemic in some parts of Europe, particularly of Russia, Germany, and France, and exists also in the United States. A conception of its extent may be derived from the fact that in one Russian district alone there perished in 1867-70 fifty-six thousand domestic animals—horses, cows, and sheep—and five hundred and twenty-eight human beings. In 1770 there occurred an epidemic in the West Indies, in which, within six weeks, fifteen thousand men died from eating beef infected with this parasite (Law). Sheep appear to be the natural host of the bacillus, since they are affected during the entire year, while other animals exhibit the disease only sporadically. Anthrax is both contagious and infectious; is acquired by cattle in grazing in certain localities, particularly after inundations, and in spots where animals similarly infected have grazed; may be probably acquired through the agency of flies. By man the disease is contracted through contact with infected animals, flesh, hides, wool; by eating infected meat.

These clinical facts were established long before the discovery of the bacillus; and have become intelligible and coherent only since the life-history of the parasite has been studied—for it is demonstrated that this plant produces spores, which, when placed under favorable conditions, grow into the mature form; but which, meanwhile, may remain in this embryonic state for an indefinite number of years, unaffected by extremes of temperature, by many chemical agents, even absolute alcohol. The mysterious and inexplicable sporadic appearance of the disease is at once explained. These

spores may be transported in the hide, the wool, and the flesh of the animal, either of which may, therefore, cause an outbreak of the disease in a distant part of the world, and after the lapse of years. It is reported that anthrax once appeared among the workmen in an upholsterer's shop, limited to those who were engaged in repairing certain chairs, imported from a distance, which were stuffed with horse-hair. Some time ago a whole family in Scotland acquired the disease after eating soup made from beef by several hours' boiling. A local epidemic occurred in Paris among the workmen who had handled a cargo of hides from South America.

Fig. 8.—Kidney of rabbit; anthrax bacilli in the inter-tubular capillaries, $\times 700$. (Copied, by special permission, from a photograph by Dr. Koch.)

The natural habitat of the anthrax bacillus has not yet been discovered, though the plant is evidently indigenous only in certain limited districts. Koch's researches, as well as clinical observations, make it extremely probable that the bacillus is not properly a parasite of animals; that it, like many other fungi, grows upon living or dead vegetable matter, and its entrance into the cow or sheep is merely incidental to the consumption of its host as food by the animal—an accidental excursion from its usual life history—just as the presence of the trichina spiralis in the human subject is incidental to the consumption of uncooked pork.

When we reflect upon the close clinical resemblance between anthrax and certain other infectious diseases; their occurrence sporadically and epidemically; their usual limitation to certain conditions of climate and of soil; their especial prevalence during certain seasons of the year; the predisposing influence of heat and moisture; the stage of incubation; the contagiousness; the self-limitation of the disease, etc., it becomes evident to every one whose cerebral functions are normally performed that there may be, in this matter of bacteria, vastly more than the optical delusions of a microscopist, the impractical fancies of a pathologist; more than fat-crystals and fibrin threads. Yet it is understood that there may be no conclusions by analogy. Anthrax and septicemia may be very similar clinically and anatomically, yet the demonstrated parasitic origin of the one does not prove the same for the other; arguments of that sort have no place in exact science. The matter must be investigated in the case of each disease independently, precisely as it has been in anthrax—a fact which is insisted upon by no one more persistently and emphatically than by Koch—to whom, by the way, we are indebted for most of what we now know about the life-history of the bacillus anthracis. And just here is another of those vital differences which distinguish Koch's work from that of Klebs and of Pasteur. The latter seem to assume the parasitic origin of the infectious diseases, and their deductions are

but too often partially based upon such assumption. Koch assumes nothing, furnishes ocular demonstration of his assertions and uses all his influence, by precept and example, to raise this subject of bacterial investigation from the mire of uncertainty, doubt, skepticism, and contempt to the firm basis of exact science. For our patience has been so sorely tried, our confidence so often abused, that we have acquired a certain indifference to bacterial discoveries; we often fail to discriminate according to the evidence furnished, and regard all alike as essentially uncertain and obscure.

In this failure to discriminate between evidence and evidence, between assertions and assertions; in this failure to distinguish between a *deduction* and a *demonstration*, is to be found, in part at least, the explanation of the remarkable attitude, or rather variety of attitudes, maintained by the medical public of our land, and of our land only, on the question to be next discussed—tuberculosis. All pathologists worthy of the name, and I believe all others also, are agreed that the miliary tuberculosis of man is anatomically identical with the disease caused by the same name in rabbits, guinea-pigs, dogs, and cats; and that pulmonary consumption results from the aggregation and degeneration of miliary tubercles.

From the earliest times there seems to have been a suspicion among medical men that tuberculosis is a communicable disease; now and then an instance was observed in which a previously healthy individual, of non-consumptive stock, became tuberculous after assuming an intimate relation—as of husband or wife—to a consumptive individual; and domestic animals, even those not particularly susceptible to the disease, such as dogs, became in some instances consumptive after close attendance upon a human subject previously so afflicted. Yet the evidence of such cases, however suggestive, was not decisive; so difficult is the proof of inoculation, so insidious and gradual the inception and manifestation of the disease, so numerous and diverse the other influences to which the individual is exposed, so impracticable the restriction of personal liberty necessary for accurate observation, that the exclusion of other possible causes for the disease has not been, and probably cannot be, conclusively demonstrated in the human subject. Clinical observations have therefore never been decisive, either affirmatively or negatively. With experiments upon animals it is evidently otherwise; and this question was, early in the history of experimental pathology, submitted to experimental investigation. In 1865 Villemin demonstrated that the subcutaneous introduction of tuberculous human tissues was followed by local and general tuberculosis in rabbits and guinea-pigs. His results were in succeeding years corroborated by Klebs, Lebert, Waldenburg, Cohnheim, Fränkel, Tappeiner, Orth, Bollinger—in short by all who made the experiment; yet not every inoculation was successful: the animals most frequently subject to spontaneous tuberculosis—especially the rabbit and guinea-pig—were found also most susceptible to inoculation; those which rarely exhibit the disease spontaneously—the dog and cat, for example—often resisted attempts at artificial induction of the disease; this was to be expected, and was considered, indeed, as clinical confirmation of the anatomical evidence as to the identity of the spontaneous and the induced disease. Tuberculosis can, therefore, according to the unanimous testimony of observers, be induced by inoculation with tuberculous tissue. But it soon became doubtful whether this unquestioned fact could be interpreted as proof that there is anything specific about the tubercle; for it is evident that if all the effects produced by inoculation with tubercle can be just as certainly induced by non-tuberculous materials, no assumption of specific nature is necessary. It was demonstrated by Burdon-Sanderson, Wilson Fox, Martin, Waldenburg, Cohnheim, Fränkel, that after the introduction of mechanical or chemical irritants—a piece of wood or paper, a linen thread, a cork, glass, pepper,

cantharides—in short, after the induction of irritation and inflammation in the subcutaneous tissue or peritoneum, an eruption of miliary tubercles, indistinguishable histologically from those following inoculation with tuberculous matter, often occurred. It is a little strange, by the way, that Dr. H. F. Formad, in a recent paper, called “The Bacillus Tuberculosis,” in which he relates the repetition of these experiments by himself and by one of his own pupils, makes no allusion, direct or indirect, to this work to which I have just referred. This is doubtless an unintentional oversight; yet in consequence of this oversight, the casual reader derives the impression that a fact demonstrated by a score of observers in the last fifteen years was discovered two years ago in Philadelphia.

And then arose the school, represented among pathologists by Buhl and Cohnheim, and among clinicians by Niemeyer, who were inclined to deny altogether the specific nature of tuberculosis, who saw in the etiology of this disease only the caseous degeneration of an inflammatory product, a conception tersely expressed in the phrase—no cheesy product, no tuberculosis. Dr. Formad, after repeating these experiments, has recently arrived at the same conclusion; but, by a repetition of the singular oversight already mentioned, he conveys the impression, by his failure to mention Niemeyer, Buhl, and the rest (though citing one of his own pupils) that this doctrine is new.

Experimental investigation, however, revealed certain facts that demolished the Cohnheim-Niemeyer theory entirely, as admitted by Cohnheim himself.

It had long been observed that wild animals, which in their native state are not known to suffer from tuberculosis, are prone to the disease when kept in confinement; and that some tame animals, when closely confined, as is usually the case in physiological laboratories, exhibit an excessive mortality from this disease. Klebs suggested that the successful induction of tuberculosis after the insertion of glass, wood, etc., might after all be simply infection from contact with animals already tuberculous, or from tuberculous materials left in laboratories by previous subjects of the disease. Cohnheim repeated his experiments on rabbits and guinea-pigs, isolated both from other animals and from the stalls in which animals had been previously confined. The subcutaneous or intraperitoneal introduction of mechanical and chemical irritants was under these circumstances followed by tuberculosis—in *not a single instance*. Fränkel, who had performed with Cohnheim the original successful experiments in the Berlin Pathological Institute, repeated them in his private dwelling, with *absolutely negative results*. Cohnheim, with the moral courage born of true scientific spirit, published this fact, and acknowledged the justice of Klebs' suggestion.

Chauveau, Aufrecht, Bollinger, and others proved that tuberculosis can be induced in rabbits and other animals by simply mixing with their food tuberculous material, and that this tuberculosis begins not in the lungs, nor in some caseous inflammatory product, but directly in the intestinal wall. Giboux placed healthy rabbits in cages in each of two rooms; into one room was passed, for several hours a day, the breath expired by phthisical patients; into the other room the same, after filtering through carbolized tow; in a few months the rabbits in the first room were dead of tuberculosis; in the second apartment there was no sign of death nor of tuberculosis. Tappeiner, and after him Bertheau, demonstrated that the inhalation of sputum from phthisical patients in minute quantity is followed by pulmonary, and then general tuberculosis, not only in rabbits, which are so susceptible to the disease, but even in dogs; and that the inhalation of other sputum did not produce this effect. On the other hand, Schottelius observed among the inflammatory products following the inhalation of irritant particles, such as malodorous cheese, certain nodules histologically identical with spontaneous tubercle; and that similar nodules sometimes followed the

prolonged inhalation of non-phthisical sputum in large quantity. (Schottelius, by the way, has since acquiesced in the infectiousness of tuberculosis.) Weichselbaum found a few similar nodules in the lungs of one of three dogs treated in this way, but no tuberculosis. He found further, that the inhalation, even when brief, of phthisical sputum induced general tuberculosis; but after boiling, or after treatment with corrosive sublimate, the same sputum produced no tuberculosis, and rarely, if ever, nodules.

These inhalation experiments—of Tappeiner, Bertheau, Schottelius, and Weichselbaum—illustrate admirably from the experimental side what had been for years acknowledged from the histological standpoint: that there is nothing characteristic in the individual nodule. The same histological structure, including the giant-cell, may be found in the nodules of syphilis or lupus, as well as of tuberculosis; the same local anatomical change may follow the inhalation of large particles of Limburger cheese, as the inspiration of atomized phthisical sputum. For decades the pathologists from Virchow down, their eyes full of caseous matter and giant-cells, wrestled with one another over the question, what is true tubercle? Their hair-splitting disputes remind us of the bitter controversies of the mediæval philosophers as to how many spirits could stand on the point of a needle. Finally it dawned upon them—they were confounding anatomy with etiology; they were regarding as characteristic of one morbid process a histological structure common to several; they were ascribing to a single cause the common effect of many; *they were confounding tubercle with tuberculosis*. As Cohnheim said years ago: “Struggle against this as we may, there is no help for it—the anatomical definition suffices no longer for the tubercle and tuberculosis.” Even Schottelius, the last of the German pathologists to deny the infectiousness of tuberculosis, has finally recorded his conviction that tuberculosis is certainly infectious, though not all individual tubercles belong to tuberculosis.

And what shall be considered a tuberculous tubercle? Wherein may we distinguish a “true” tubercle from a nodule exhibiting an identical structure? The question is answered instantly when we consider what constitutes pyæmic pus. Pus is a definite anatomical entity, varying, like tubercle, within certain limits. The pus from a pyæmic joint, may be indistinguishable by the microscope from the pus of a simple abscess; yet there is none the less a vital, or rather a fatal difference. Fresh pus from a simple non-specific abscess does not cause pyæmia, as Virchow long ago proved; a minute quantity of pyæmic pus is fatal through pyæmia, as the death of many a physician has testified. The tubercle from Limburger cheese does not cause tuberculosis, as Schottelius himself admitted; the tubercle from tuberculosis *never fails* to do so, as all observers testify. Pyæmic pus, however similar histologically to that from croton-oil or turpentine, is unerringly distinguished by its infectiousness; tubercles from tuberculosis, though anatomically identical with those from mechanical irritation or from syphilis, contain a something sure to propagate itself in the proper soil. The non-specific pus of a simple wound or abscess may acquire pyæmic properties, without the intentional or even conscious introduction of pyæmic matter; the non-specific cheesy products of a simple inflammation may acquire infectiousness without the *intentional* introduction of a specific agent. This acquisition of pyæmic infectiousness never occurs, as has long been known, without bacteria; and the day has come when we can say that the infectious tubercle—of tuberculosis—is also characterized by a bacterium.

Perhaps the clearest proof—because a demonstration—of the infectiousness of tuberculosis is furnished by comparative observations upon the eye made by Baumgarten, Cohnheim, Salomonsen, Deutschmann, and others. When the piece used for infection is fresh, Cohnheim says “the irritation at the commencement

usually soon subsides, the particle becomes gradually smaller, and can indeed entirely disappear, and for some time the eye then appears entirely clear and intact, until there suddenly appears in the iris a greater or less number of very minute gray tubercles which, precisely like the human tubercles, grow to a certain size, then become caseous, etc. In rabbits Salomonsen and I observed the eruption of the tubercles usually about the twenty-first day after the inoculation, in guinea-pigs a week earlier as a rule." "Yet these observations have first acquired their full significance from the fact that the tuberculosis is generated by the inoculation of tuberculous matter *only* and of *nothing else*." These are the words of a man who, some years ago, was inclined to the belief, from the fact that the disease may follow subcutaneous or intraperitoneal mechanical irritation, that tuberculosis was not an etiologically specific disease. In his "Allgemeine Pathologie," in discussing the same subject, Cohnheim says, "After a few days the cornea is quite clear, the iris thoroughly clean and in perfectly normal condition; in the aqueous humor there is also no exudate to be seen, so that one can see the piece introduced sharply and clearly defined against the lens capsule; and thus it remains unchanged for weeks, except perhaps that the particle becomes somewhat smaller. All at once, in our cases between the twentieth and thirtieth day, the scene changes; there arises in the iris tissue a considerable number of small transparent grayish tubercles." "Yet the most interesting feature is that in numerous instances, though not always, a more or less extensive tuberculosis of lungs, lymph-glands, spleen, and other organs, occurs. From these experiments it cannot be doubted, first, that the tuberculosis by inoculation can develop *without the medium of a coagulated exudate*, and, second, that it has a stage of incubation." He says further, "Where experiments so positive and so easy of repetition are adduced, it would seem impossible to discuss any longer the question of infectiousness."

Until, therefore, we can otherwise explain the fact that general tuberculosis can be induced by mixing small quantities of tuberculous matter (but not by mixing any other tissue) with food; by simple inhalation of phthisical sputum, but by no other sputum, nor even by this after boiling or treatment with corrosive sublimate or filtration through carbolized tow; that general tuberculosis without caseous exudate follows the introduction of a minute tuberculous particle, but of nothing else, into the eye; until it shall be possible to offer another explanation, we must admit that there is a *something* peculiar to tuberculosis and not common to all tubercles. To assert with Niemeyer that the disease originates *de novo* in a cheesy mass, is to assume that because there is no *intentional* or *conscious* introduction of an infectious agent therefore none occurs. Surely no surgeon ever intentionally or consciously introduced pyæmic matter into a wound; yet infectious pyæmia was formerly the scourge of hospitals. Septicæmia, erysipelas, diphtheria, and pyæmia are none the less infectious because there is—especially in the so-called spontaneous cases of each—no discoverable possibility of contact with previous subjects of the same disease. *Infection*, in other words, does not necessarily imply *contagion*. No man becomes syphilitic unless there be incorporated into his body material from an individual previously syphilitic; no man acquires scabies without contact with a sufferer from itch; but pyæmia, erysipelas, diphtheria, anthrax, and tuberculosis are acquired not only by transfer from subjects of the respective diseases, but also without such transfer. The purulent secretions of a wound are doubtless favorable soil for the retention and propagation of pyæmic or erysipelatos virus; the catarrhal products in the throat for the origin of diphtheritic infection; the cheesy products of a bronchitis or of mechanical irritation for the location and propagation of the tuberculous infective agent; *but none of these are necessary*. Pyæmia, erysipelas, diphtheria, anthrax, tuberculosis occur not only by demonstrable con-

tagion, not only after a simple wound without demonstrable contagion, but also *without either demonstrable contagion or even a simple wound*—i.e., spontaneously.

Yet in the face of this perfect analogy with other infectious diseases, in the face of the experimental proof as above related, there are doubtless many practising physicians who cannot believe that tuberculosis is communicable. Why? First, because clinical proof to that effect is unsatisfactory; a surgeon pricks his finger in dressing a pyæmic patient, and in twenty-four hours has a chill and local symptoms pointing unmistakably to the source of infection; a physician inspires the breath of a struggling diphtheritic patient, and in three or four days gives evidence that the disease was communicated. Had tuberculosis ever been observed to occur in animals so soon or so violently, were the introduction of tuberculous as well as of pyæmic and erysipelatos virus accompanied by chill, fever, and severe acute local inflammation (it does seem to be so accompanied in general acute miliary tuberculosis), there might be reason in the objection that no absolute clinical proof has been furnished. But even when the freshest of tuberculous material is introduced into the most favorable soil, the eye of a susceptible rabbit, two to four weeks elapse before the first local manifestation of infection, and further weeks or months before the evidences of general tuberculosis are apparent; there is, indeed, nothing in the animal's history to indicate infection, the proof of which consists merely in the conscious act of inoculation. An observer who was not aware of this act, might honestly believe that the infection which manifests itself weeks or months later is spontaneous—even autochthonous; and some physicians, because they see no transfer of tuberculous material (though opportunities enough for such transfer are certainly given), because they see *no striking symptoms to mark the hour or the day of infection*, insist that no infection has occurred.

A man may be shot in the presence of witnesses; but if we find a body with a bullet in the heart, we are none the less certain that this body, alive or dead, has been shot, though no revolver nor human agent may be discoverable. A man may be killed by the lightning which dazzles all eyes; but he is none the less killed if the electricity be the invisible current of a powerful battery. If a man exhibits secondary syphilis, nothing can shake our conviction that he has, whether consciously or not, come into contact, mediate or immediate, with a syphilitic person, although the sufferer himself may be honestly unable to point out the moment or the mode of possible infection. In many cases of pyæmia and diphtheria the course of the infection is as plain as the track of the lightning; the effect as pronounced and almost as sudden as that of the murderer's bullet. In other cases, however, of pyæmia, diphtheria, as well as of anthrax, syphilis, and tuberculosis, there are absolutely no phenomena observable in the individual which attract attention to a given moment as the time at which an infection, subsequently manifested, may have occurred. A piece of tuberculous matter introduced into a rabbit's eye may entirely disappear; and for weeks the animal presents absolutely no signs, local or general, of tuberculous infection.

The opportunities for the usual mode of infection by syphilis are only occasional; and the attendant circumstances are such as to impress such occasions upon the mind and conscience; when, therefore, the first evidence of infection appears, perhaps weeks subsequently, upon that part of the anatomy peculiarly exposed upon such an occasion, it is but natural that the mind should associate the two phenomena as cause and effect. Were syphilis communicated not in the way at present in vogue, but by inhalation; were the initial evidence of infection not upon the integuments and therefore visible, but in the lungs and hence inaccessible to the eye, there might be the same clinical grounds for doubting the infectiousness of syphilis as of tuberculosis. The occurrence

of infection in tuberculosis is usually as unobserved clinically as in the exceptional cases of syphilis, in which a primary lesion was neither suspected nor discoverable.

Another argument often heard against the infectiousness of tuberculosis, recently uttered and printed by a Philadelphia surgeon, is the fact that we do not all die of this disease. Yet the same argument is valid against the infectiousness of cholera, yellow fever, diphtheria, scarlatina, etc. Indeed, since the death-roll of tuberculosis is greater, year after year, than that of any one or perhaps all of these diseases combined, the argument, if it had any sense at all, would tend to prove the excessive infectiousness of tuberculosis. Such an argument ignores the unquestioned and familiar fact that we are not all equally susceptible to any one of the infectious diseases; even the most malignant cholera or yellow fever attacks only a portion—usually a decided minority—of the community. Explain it as we may, there is a something which we may call predisposition, by virtue of which only certain individuals yield to infection by cholera or by tuberculosis; and the fact is, that the number susceptible to tuberculosis seems smaller than to any one of several other infections. Comparatively few of us attain maturity without having had measles, scarlet fever, and whooping-cough at least; yet six-sevenths of us complete our pilgrimage without exhibiting evidences of tuberculosis. That this is not mere accident is shown by experiment: guinea-pigs and rabbits rarely, dogs and cats usually fail to respond with general tuberculosis to inoculation with tuberculous material. Even the deadly anthrax usually fails to destroy carnivorous animals, although the most virulent material is introduced; and it was long ago pointed out by Chauveau, and often confirmed, that although sheep are very susceptible to this disease, yet some sheep resist all experimental attempts at inoculation, even when large quantities of fresh anthrax material are injected into the animal. Dogs enjoy in general immunity against infection by anthrax; yet young dogs are often successfully inoculated. Infection implies, therefore, not simply a virus capable of propagation in an animal, but also an animal capable of permitting such propagation. All variations of this relative adaptability may be exhibited between animals of the same species and a given virus. To affirm, then, that a disease—anthrax or tuberculosis, for example—is infectious is to assert that it can be communicated by the diseased to a healthy animal, not to all healthy animals, even of the same species. Herein lies evidently our security against tuberculosis, as well as against many other infectious diseases. The general principle—the survival of the fittest—seems to have been for generations at work in eradicating this disease from the human family, by removing those members of it susceptible to tuberculosis; the great majority of us now living are as safe from tuberculosis as most dogs are from anthrax.

Another, perhaps the most profound, argument against the infectiousness of tuberculosis should be considered here, namely, that the fact must cause us to relapse into barbarism. "Some of the most noble and tender traits of humanity threaten to be undermined. The consumptive who has been heretofore lavishly loved and cared for," etc., "is to be isolated and shunned as a leper, if such doctrines prevail" (*Philadelphia Medical News*, January 27th, p. 94). Therefore tuberculosis is not infectious. Incredible as it may appear, the author of these lines is not a clergyman nor a poet, but a distinguished surgeon who does not shun infectious pyæmia, septicæmia, and erysipelas; and who, we may assume, does not love his child less lavishly, nor care for his patient less faithfully because that child or patient may suffer from infectious diphtheria or scarlatina.

Were the susceptibility to tuberculosis as general as to diphtheria, scarlatina, and measles, there might be grounds, not for shunning the consumptive "as a leper," but for the observance of proper precautions for the protection

of the healthy many, even at the inconvenience of the diseased few. But since the experience of generations has shown that only about one-seventh of us acquire tuberculosis even with unrestrained intercourse with consumptives, it may be questionable whether any other protection than a knowledge of its infectiousness for some individuals be necessary; we do not invoke the law to brand syphilitic individuals, though to this infection not one-seventh but, probably, all of us are susceptible. But, however that may be settled, let us not confound a fact with a possible deduction which may be unpleasant.

These more or less prevalent arguments against the infectiousness of tuberculosis have been considered not because they have any bearing upon the question, but because there are those who will not or do not take into consideration the demonstrations attained by accurate experimental methods, and whose opinions rest upon distorted deductions from necessarily inaccurate clinical observations. Yet while those who are pleased to regard pathology as something extrinsic to practical medicine are still discussing the clinical proofs of the infectiousness of tuberculosis, it is quite otherwise with pathologists and clinicians whose opinions are founded upon knowledge without prejudice. One after another the German and French pathologists (who are not infrequently clinical teachers as well), honest in their previous conviction that the communicability of tuberculosis was not proven, honestly recorded their convictions as succeeding proofs were furnished, that the case was reversed; so that three years ago Cohnheim said, "To-day there scarcely exists a pathologist who would deny that tuberculosis is a communicable disease."¹

Cohnheim himself, extending and repeating more carefully his observations, saw and acknowledged the error of his former deduction. True, a would-be pathologist has occasionally reminded us that he was not yet convinced; yet even Schottelius, the last of them, has finally yielded the point. There have been in all ages, and on all questions, similar psychological curiosities; twenty-five years ago it was maintained on the floor of the French Academy of Sciences that intestinal worms originate *de novo* in a peculiar influence pervading the system—the vermicular diathesis. There is a gentleman in this State who recently reminded us that bacteria, so-called, are in his opinion fibrin threads and the like; and there is said to be a man in Virginia who still insists that the earth is flat.

You may have noticed that in this discussion the name of Koch has not been mentioned—a fact to which I call attention, because a popular impression, not entirely confined to the laity, saddles upon Koch the paternity not only of the bacillus, but also of the infectiousness of tuberculosis. Dr. Formad, for example, says (p. 3): "An analysis of Koch's experiments shows that he has not proved the parasitic nature of tuberculosis, so that the infectiousness of tubercular disease is still *sub judice*." It is apparent from the facts which I have endeavored to summarize that the communicability of tuberculosis was established years before the well-known publication of Koch's discovery. Dr. Formad says (p. 10): "The supreme question before the medical world is now, whether the disease under consideration is really infectious." This statement may represent faithfully that portion of the world bounded by the city limits of Philadelphia; the supreme question before that portion of the medical world including Virchow, Cohnheim, Billroth, Bamberger, Weigert, Villenin, and the other German, French, and Austrian pathologists and clinical teachers is, *not* whether tuberculosis is infectious, but whether the bacillus of Koch is the infective agent. For them the two questions are quite independent—the former established, the latter awaiting confirmation.

(To be continued.)

¹ In the *Medical News*, January 27, 1883, p. 94, Dr. Wm. Hunt leads us to infer that "most recent pathologists" agree in regarding tuberculosis as the result of a simple inflammation. Will he kindly name *one* pathologist who now holds this opinion, and mention the pertinent publication?

CONDENSING OTITIS OF THE MASTOID PROCESS.¹

By ALBERT H. BUCK, M.D.,

NEW YORK.

HYPEROSTOSIS or sclerosis of the mastoid process of the temporal bone has, until quite recently, been considered rather as a pathological condition, which is occasionally encountered in operations upon that bone, or at the post-mortem examination, than as an active morbid process possessing a sufficiently definite train of symptoms to justify us in assuming its existence in particular cases. Many a surgeon has undoubtedly bored into the mastoid process of a patient who presented almost every symptom of an incipient or well-advanced caries of that bone, and has been astonished to find its cells wholly or in part obliterated, its substance almost as hard as ivory, and no pus discoverable at any point. He is afterward pleased to find that the operation has relieved the patient of pain, and that the evidences of active inflammation have all gradually disappeared; but he has undoubtedly been not a little puzzled to find a satisfactory explanation for the sequence of well-marked pathological phenomena of which he has been a witness. A few experiences of this kind led me years ago to maintain that in the great majority of cases which seemed to call for the operation of boring into the mastoid process, we should not be able to say beforehand whether we should find the bone in a carious condition or simply congested. When I have least expected it, my drill has plunged into a well-defined collection of pus and fragments of carious bone; while still more often, not a trace of pus has been discovered in the progress of the operation. In cases belonging to the latter class I have assumed, in my desire to find some reasonable explanation of the severity of the pain and of the pronounced character of the outward signs of deep-seated inflammation, that the operation was performed at a time when the bone was still in the first stage of an inflammation which, without operative interference, would be certain to eventuate in caries. It was difficult to realize that such severe pain and such well-marked periostitis might be simply the outcome of a subacute proliferative inflammation of all those soft parts which supply nourishment to the mastoid bone—and such indeed is undoubtedly the nature of the processes which take place in cases of hyperostosis of this part of the temporal bone.

So far as I can learn, Dr. C. R. Agnew, of this city, was the first person to suggest the idea that inflammation of the mastoid cells need not necessarily tend toward caries of its bony structures. He says that he is convinced that "caries is not the invariable and immediate result of mastoid cell disease, but that sometimes there may be, instead, an ostitis, with hyperplasia of the bone, filling a few or all of the cells."² Three years later (1873), in a paper which I published on the subject of mastoid diseases, I made the following statement with regard to sclerosis or hyperostosis of the mastoid process: "While this form constitutes a distinct pathological condition, we are not yet in possession of sufficient clinical facts to guide us to a positive diagnosis. Sclerosis or hyperostosis of the mastoid process is associated with either chronic catarrhal or chronic purulent inflammation of the middle ear. Its progress is so insidious and so rarely accompanied by any marked symptoms that it is only at the post-mortem examination, or when called upon to trephine the bone, that we discover the existence of this condition. As the very delicate membrane which lines the mastoid cells serves the double function of mucous membrane and periosteum to the intercellular bony septa, it will be readily understood how a chronic con-

gestion of the membrane may result, on the one hand, in thickening of its substance, and, on the other, in hypertrophy of the bone which it nourishes. In place, then, of air-containing cavities separated by thin septa of bone, we find a tolerably dense bony mass, whose substance is studded throughout with small collections of slightly vascular connective tissue." It was not, however, until at a still later date that any attempt was made to hazard a diagnosis of this condition. In 1876, and again still more recently, Dr. J. Orne Green, of Boston, Mass., published reports of cases in which he had made, and verified by operation, the diagnosis of hyperostosis of the mastoid process.¹ Finally, in 1879, Arthur Hartmann, of Berlin, Prussia, published a paper from which it appears that he also had arrived at the conclusion that sclerosis can appear as an idiopathic disease of the mastoid process, after cessation of inflammation of the middle ear, and cause the most violent pains.²

The preceding brief statement furnishes, I believe, a correct account of the progress of our knowledge with regard to this pathological process. It is also a fact that, even at the present time, this knowledge is still available only in a vague and disconnected form. It is my purpose to see how far I can succeed in bringing these fragments together into a logical whole, in the hope of thus reducing to order some of the confusion which now exists. The blame for a part of this confusion, as I can now see, may justly be laid at my own door, for in the paper which I published in 1873, on the subject of mastoid diseases, I endeavored to establish different forms of disease for what were in reality simply phases of one and the same pathological process. Another part of the confusion is to be attributed to the fact that very few of the cases reported as illustrations of hyperostosis of the mastoid process are sufficiently free from complications to render them useful as types. The pictures drawn are undoubtedly true to nature, and the expert assents at once to the correctness of the diagnosis, but the student, or the physician who sees such cases only at long intervals, would perhaps fail to appreciate what are the particular features which distinguish hyperostosis from ulcerative or carious disease of the mastoid bone. Finally, I am disposed to attribute some of the confusion to the terms which we commonly employ in speaking of the disease, viz., hyperostosis, sclerosis, and osteo-sclerosis of the mastoid process. The idea of active inflammatory changes is not embodied in any of these terms; but rather that of a pathological change which has reached completion, and has therefore ceased to be active. I much prefer the expression *ostitis* (as used by Dr. Agnew in the paper referred to above), which implies an activity of the inflammatory or hyperplastic processes; and, in order to convey at the same time the idea that the inflammation tends toward solidification, rather than toward destruction of the bone, I should be disposed to add the qualifying term *condensing*. While I have ventured to put this expression—condensing ostitis of the mastoid process—at the head of this paper, I have made no attempt to employ the term exclusively, through fear that I might create further confusion in the minds of those readers who are familiar only with the expressions commonly used.

Among a number of cases which have from time to time come under my observation, I have seen but two in which the two things required to render them suitable as types—viz., a maximum degree of hyperplasia of the mastoid process, and a minimum degree of activity of all disturbing complications—coexisted. One of these cases is still under observation, and consequently my history of it must necessarily be incomplete. The other, though seen more than ten years ago, and reported at the time, has always been more or less of a puzzle to

¹ Hyperostosis, sclerosis, or osteo-sclerosis of the mastoid process.² Report of the American Otological Society, 1879.¹ Report of the International Otological Society, 1876; Transactions of the American Otological Society, 1880.² Archives of Otology, 1879.

me, until I came to reflect upon it while reading Dr. Green's papers. The histories of these two cases are as follows :

CASE I.—The patient, a lady, about thirty-five years of age, consulted me on March 30, 1880, on account of a discharge from the right ear, and frequent attacks of pain throughout the right side of the head. I was not able to obtain a very full account of her previous history, so far, at least, as it related to the affected ear; but as the result of my cross-questioning, I ascertained that the disease had begun in early childhood, as an acute purulent inflammation of the middle ear; that it had then run an irregular course, lighting up at long intervals into an acute exacerbation, and then subsiding again into a comparatively quiet state; that there had always been some discharge from the ear, at one time very scanty, at another quite copious; and that the disease had finally, during a period of ten or twelve months, immediately preceding the time when I first saw her, settled down into a steady discharge from the ear, associated with frequent and sometimes quite severe attacks of pain involving the right side of the head. The affected ear still possessed a useful degree of hearing. An examination with the speculum and reflected light revealed the existence of a thick laminated mass of epithelium, pus, and cheesy matter, occupying the deeper part of the external auditory canal. Fresh pus was oozing out from beneath the mass. By aid of the curette, a slender silver probe, and a mop of cotton wound around the end of a cotton-holder, I was able to clear away all these old and foul-smelling products of inflammation, and to obtain a clear view of the diseased region. About two-thirds of the membrana tympani still remained, and the greater part of the discharge evidently came from the mastoid antrum, the tympanic mouth of which was partly blocked by a small polypoid growth. I removed this growth with the wire loop and Blake's snare, and advised the patient to use regularly, for a short time, the douche with lukewarm water. My scant notes say nothing about the condition of the mastoid process; and from this I infer that I must have overlooked certain conditions which very probably existed at that time, but which I did not discover until later.

On March 8, 1882, or nearly two years later, the patient again consulted me. During this long interval the ear proper had given her very little trouble, and there had only been an occasional slight discharge, but she had still continued to be subject to periods of pain involving the right side of the head, and occasional attacks of flushed face. During the previous week, however, the pain had been quite severe and had localized itself more particularly in the ear. She had also experienced considerable dizziness at times. I examined the ear and found that the desquamative process had a second time produced a tough plug that filled the deeper end of the meatus. I also found, by aid of a bent probe, that the upper part of the tympanic cavity, posteriorly, was filled with a rough white mass of laminated epithelium. It was only after prolonged efforts, made partly with the bent probe and partly with a douche provided with a slender glass end-piece, bent at a right angle, that I finally succeeded in completely freeing the cavity from the offending masses.

A sharp inflammation followed this prolonged operative interference. It spread along the cutaneous lining of the external auditory canal, and caused it to become greatly swollen; it extended along the Eustachian tube, and rendered the act of swallowing painful; and, finally, it involved the cellular tissues behind, above, and in front of the ear. Throughout all these outer regions tenderness on pressure, redness of the surface, and decided œdematous swelling were noticeable already on March 10th. The body-temperature was 102° F. The application of hot poultices having failed to afford much relief from the pain, I made a Wilde's incision and divided the mastoid periosteum freely. I also prescribed the frequent application of hot flax-seed meal poultices.

On the following day I found the patient in a more comfortable condition, but there was still a great deal of inflammation all around the ear. Three leeches were applied behind the ear, and the continuance of hot applications was advised.

On March 12th I found more decided evidences of the subsidence of the inflammation.

On the 13th the body-temperature was 99° F., and the patient expressed herself as feeling fairly well again. A small amount of pus constantly escaped from the auditory canal, and its walls were still so much swollen that I could not obtain a satisfactory view of the deeper parts. The tenderness, however, had almost entirely disappeared, except immediately over the mastoid region.

About the middle of April I removed another polypoid mass of granulations from the tympanic orifice of the antrum, and from that time forward the discharge ceased altogether.

On May 10th I made a careful examination of the ear, and found that all those parts of the middle ear which could be seen, were pale, dry, and perfectly free from the slightest trace of congestion. So far as I could ascertain by means of the bent probe, the antrum and the posterior upper portion of the tympanum were empty. The cutaneous walls of the auditory canal were also perfectly free from either redness or swelling. Behind the ear, however, the skin was noticeably red, and firm pressure with the finger, at almost every point over the mastoid process, caused some pain. These parts were at the same time slightly œdematous. On comparing this region with the corresponding one on the other side of the head, I discovered, for the first time, that the right mastoid process was appreciably larger than the left. On simple inspection it seemed to be markedly larger, but on palpation, and after making due allowance for the œdematous condition of the integuments, I became satisfied that the difference in size was only moderate in degree, though yet unmistakable. As the patient was still subject to almost constant pain in the region behind the ear, and in fact throughout the entire right side of the head, I applied three leeches directly over the right mastoid process, and allowed the after-bleeding to go on unchecked for a considerable time.

On October 6th I again had an opportunity of examining the patient's condition. She reported that the local blood letting referred to in the preceding paragraph, had afforded her decided relief from pain for a period of several days. The pain had then returned, and all through the summer she had experienced more or less of it, not constantly, but yet very frequently. Blisters had also occasionally been applied over the mastoid region, but without any beneficial effect. Notwithstanding the persistence of the pain, she had had the best of health in all other respects. On examination, I found the deeper parts of the ear in a perfectly quiet state, and free from even the slightest evidence of inflammation. On the outside, however, the previously described condition of redness, tenderness, and slight œdema still persisted. In fact, the tenderness extended as far back as the occipital protuberance. As the pain had been more acute than usual, during the previous three or four days, I advised a repetition of the local blood-letting. (The patient has since moved away from the city.)

CASE II.—A physician, a resident of South Carolina, fifty-six years of age, and of a strong constitution, consulted me on October 6, 1872, for a painful affection of the ear. He gave the following history: In 1835 he contracted an acute inflammation of the left middle ear from the violent concussion of the air caused by the bursting of a gun. The severe symptoms soon passed away, but the purulent discharge from the ear continued for some time afterward. Then, for a period of many years, he experienced no trouble beyond a moderate degree of deafness and some tinnitus. The perforation in the drum-membrane remained unclosed

through all these years. About twelve weeks before the time when I first saw the patient, he noticed that there was a slight watery discharge from the left ear, which was at the same time somewhat painful. The pain became gradually more severe and was associated with headache and fever. The doctor bled himself to the extent of about sixteen ounces; six hours later he took from the arm an additional quantity of about eight ounces. A profuse suppuration from the ear soon took place, and the pain then became less severe. For a month no marked change occurred in the condition of the ear. The discharge continued, though at times it would almost cease. On August 23d he had a rigor, which was followed by a return of all the acute symptoms. The pain was referred to the base of the brain, the mastoid process, and the articulation of the jaw, and was very severe. Bleeding to the amount of twelve or fifteen ounces afforded some relief, and the discharge again became abundant. For a week the pain remained moderate. On August 31st he had another rigor, followed by intense pain, referred to the mastoid process, whence it extended backward toward the occiput and occipito-vertebral articulation; in fact, the whole side of the head was painful. There was tenderness over the mastoid process, and the auricle was pushed out somewhat from the head. On September 18th, no material improvement having taken place in his condition, the doctor started for New York, in the hope of obtaining relief there. The sea-voyage from Charleston benefited him very decidedly. The severe symptoms abated, and, for some time after reaching this city, he enjoyed, at least during the day, comparative comfort; toward night, however, the old trouble returned with greater or less severity. During the few days preceding his visit to me, he suffered acutely from pain in the region of the ear. On examination I found the meatus in a normal condition, the membrana tympani perforated anteriorly, the Eustachian tube freely open, and only a trace of pus in the middle ear. The mastoid integuments were cedematous and tender on pressure. The tenderness also extended back toward the occiput. General condition fair: pulse a little accelerated; no heat of skin. At a consultation held by Dr. James R. Wood, Dr. Hermann Knapp, and myself, it was deemed best to perforate the mastoid process. At the patient's own request the operation was performed without the aid of an anæsthetic. The appearance of the bone, after the periosteum had been divided and lifted to one side, was entirely normal. The drill was applied on a level with the upper wall of the meatus, and was made to penetrate to a depth of three-fifths of an inch without encountering the characteristic cells. At this depth, however, a tolerably firm pad of connective tissue was felt. It was supposed at the time that this mass filled the antrum, but on subsequent inspection I became persuaded that, owing to the thickness of the swollen integuments and the recumbent position of the patient, I had erred somewhat in the direction which I gave to the drill, pointing it too far backward. The pad of connective tissue was undoubtedly the outer wall of the lateral sinus.

October 13th.—Patient passed a comfortable night. Pain much less than before the operation. Ordered quinine, gr. vj. daily.

October 14th.—Pain again severe. Consultation with Dr. Robert F. Weir and Dr. Hermann Knapp. A second perforation was made with the drill, this time nearer to the meatus and on a somewhat lower level than the first. The mastoid cells encountered were small and congested, but no pus was found. Tent inserted: poultices.

October 15th.—Slight improvement.

October 16th.—Pain diminishing. Temperature, 97° F. Free discharge from wound.

October 17th.—Marked improvement in every respect. Application of poultices to be discontinued.

October 23d.—Tenderness over mastoid process almost gone.

November 14th.—Patient is quite well again. There is no discharge from the meatus, and the wound behind the ear has healed except at two points, corresponding to the two perforations in the bone.

A few weeks later I heard from the patient, who had returned to his home, that he had remained free from pain, and that his general health was quite good again.

To these two cases I wish to add one reported by Dr. J. Orne Green. While it is comparatively free from disturbing complications, and therefore admirably adapted to serve as a type for purposes of study, I cannot help believing that this patient, at some earlier period of his life—perhaps many years before the occurrence of the acute attack which, according to the history given, apparently afforded the exciting cause of the mastoid hyperostosis—must have had a prolonged inflammation of the middle ear. The history of this case is as follows:

CASE III.—“Another case in which osteo-sclerosis existed, and was proven by operation, was that of a man seen in 1878. He was about thirty-five years of age, previously healthy; one week before he began to have pain in the left ear, followed by discharge two days after, and severe vertigo with vomiting and great weakness; there were also subjective noises as of hissing. Examination showed purulent inflammation of the tympanum with a minute perforation, which was enlarged with a paracentesis needle so as to give free evacuation. A few days after there was a slight paralysis of the left facial nerve. The inflammation of the tympanum subsided under treatment, the perforation healed, the paralysis disappeared, and at the end of two months the ear was apparently well, but the deafness was absolute on that side. Pain in the mastoid and over the side of the head continued, however, with slight tenderness of the mastoid on deep pressure, but without any swelling of the soft tissues; no enlargement of the bone was perceptible. Other means failing to relieve the pain, the bone was perforated under ether with a triangular borer to the depth of half an inch: no pneumatic cells were reached, the bone throughout being dense and ivory-like. The relief from the operation was gradual, but decided, and the patient made a good recovery. In this case also there was no reason to suspect syphilis.”

In the first of these cases the pathological events succeeded each other in the following order: purulent inflammation of the middle ear occurred in childhood, with destruction of a part of the membrana tympani; the inflammation did not entirely subside, but continued for years afterward, in a chronic subacute form, with occasional exacerbations. From the antrum, as the centre of its greatest activity, the inflammation spread to the pneumatic and diploëtic portions of the mastoid process and caused an active hyperplasia of this bone. During the continuance of this otitis the patient suffered from pain in the mastoid region and vicinity. At first the paroxysms of pain were of comparatively short duration and the intervals of freedom from pain lasted weeks or even months. Later, however, these painful attacks lasted for days, and finally even for weeks, and they recurred more frequently. In addition to the pain, in this later stage of the disease, certain external manifestations showed themselves, viz., redness, swelling, and tenderness of the mastoid integuments, and even an appreciable degree of enlargement of the bone itself. Furthermore, while at first the mastoid otitis required an exciting cause, in the shape of a more or less active inflammation of the middle ear proper and antrum, to keep it alive, in the later stage of its existence no such stimulus seems to have been required, inasmuch as the complete arrest of the inflammation of the middle ear and antrum by treatment, failed to restrain, in apparently the slightest degree, the diffuse mastoid otitis, which had already gone so far as to cause visible enlargement of the bone.

A similar synopsis of the second case shows much the

same sequence of pathological events. In early manhood a violent concussion of the air seriously damaged the middle ear, leaving it for a long time the seat of a purulent inflammation. Probably during this period a certain degree of subacute mastoid otitis was associated with the affection of the middle ear. For a period of many years all these parts remained quiet and free from all diseased action. Then, under some provocation which does not clearly appear in our history of the case, the middle ear again became the seat of a violent inflammation lasting several days, and afterward lighting up once or twice into exacerbations of marked severity. A fresh otitis was thus started in a mastoid process whose cells were probably already much reduced in size by the previous attack. For a period of several weeks it was kept in a state of activity by the continuance of the acute inflammation in the middle ear. Finally, when the latter subsided, the otitis still persisted, having in the meantime acquired sufficient momentum of its own. An artificial opening in the bone revealed the true nature of the disease, but the condition was not clearly appreciated at the time.

In the third case we find again essentially the same order of pathological events, but with some noteworthy variations. In the first place, the original inflammation of the middle ear spread, not only to the mastoid structures, but also apparently to the labyrinth, causing a total loss of the hearing of that side. Then, after the lapse of a period of less than three months, during which time the inflammation of the middle ear gradually disappeared altogether, a very decided degree of hyperostosis was found when an opening was made in the mastoid bone. In this case also the latter operation afforded decided relief from the persistent pain.

In these cases we have, as I believe, remarkably pure types of condensing otitis of the mastoid process. Many of the accidental symptoms, which are so apt to be present in these cases, and which complicate greatly the problem in diagnosis, are lacking. I refer to decided evidences of inflammation in the middle ear or external auditory canal, to fistule, to facial paralysis, to convulsions, to pyæmic symptoms, etc. When such conditions are present, the possibility of making a correct diagnosis will depend entirely upon the observer's ability to weigh nicely the significance of each of the phenomena presented, and to correctly estimate their relations to each other. This sort of work belongs to the expert, and no formulæ that I am able to lay down will materially aid an inexperienced person in arriving at the truth. I can only hope to point out those peculiar relations of symptoms to each other, which, in cases like those which I have narrated, may enable the general practitioner to arrive at a correct diagnosis. I will enumerate these distinguishing marks in the order of their importance:

First.—The persistence of decided pain in and around the mastoid region, despite the existence of an adequate outlet in the drum membrane for the pus secreted in the middle ear; despite the absence of anything like acute inflammation of the middle ear or external auditory canal; or, finally, despite the employment of such therapeutic measures as would be likely to allay any ordinary inflammation of these parts or a mere passing congestion of the mastoid structures.

Second.—The presence of such external signs as redness, swelling, and tenderness of the outer mastoid integuments, under the conditions just enumerated, furnishes strong corroborative evidence of condensing mastoid otitis. Actual enlargement of the bone itself may be considered as furnishing almost positive proof of the disease.

Third.—The history of previous chronic purulent inflammation of the middle ear justifies the assumption that the mastoid cells have already been greatly reduced in size, if not obliterated, by earlier attacks of subacute otitis of these parts.¹

Dr. Green expresses the opinion that as time goes on we shall find that cases of hyperostosis of the mastoid process become more numerous. I fully agree with him in this belief; and, inasmuch as experience seems to teach that simple non-purulent otitis is rather the rule than the exception, I would suggest that we emancipate ourselves hereafter from the idea that a purulent or carious focus is the lesion to be looked for in these painful affections of the mastoid process, and adopt rather the state of mind which will lead us to assume the existence of a simple condensing otitis. The prognosis is far less grave than in the other condition, and the indications for treatment are clear and simple. Leeches, hot poultices, and even Wilde's incision will probably fail to give more than temporary relief, and if such prove to be the case, we should not hesitate to perforate the bone with a drill or other suitable instrument. In the great majority of cases it will not be necessary to make any effort to reach the antrum. The desired relief will be equally well attained by the simpler operation of penetrating the bone, in one or, at the most, two places, to a depth of say half an inch. The relief seems to depend, not upon the establishment of an outlet for pent-up products of inflammation, but rather upon something which may be described as counter-irritation. I once tested this point in an obstinate case which presented every appearance of being one of simple mastoid otitis, and which had failed to improve under the action of blisters, local blood-letting by leeches, poultices, and, finally, Wilde's incision. I repeated the latter operation, and, as soon as the bleeding had ceased, I freely applied the stick of nitrate of silver to the raw surfaces, down to the very bottom of the wound. The vigorous inflammation thus set up effected a perfect cure of this painful affection, and satisfied me that the beneficial effects of the decidedly less barbarous method of boring into the mastoid bone, may in large measure be attributed to counter-irritation.

THE DANGER ATTENDING THE USE OF ETHER AS AN ANÆSTHETIC IN CASES OF BRIGHT'S DISEASE.¹

By R. VAN SANTVOORD, M.D.,

NEW YORK.

THE fact that the employment of the comparatively safe anæsthetic, sulphuric ether, is not entirely free from danger has been attested by the record of a number of fatal accidents occurring from its use. In some of these cases death has taken place during anæsthesia, in some cases the action of the heart, in others respiration, first ceasing. In others consciousness has been restored but the patients have passed into collapse some hours after its administration. In these cases there has usually been no distinct organic affection on which could be laid the blame of the accident. Fright during the commencement of the inhalation, as is known to be the case with other anæsthetics, may account for some of them. It is possible that the shock of the operation during *imperfect* anæsthesia, as Mr. Lister claims to have observed under chloroform ("Holmes' Surgery"), may have caused deaths which were attributed to ether, but which would in reality have been *prevented* by the ether had the anæsthesia been more profound. Death occurred in some cases in

lent inflammation of the middle ear. From a study of fifty of Schwartz's cases (published at different times in the *Archiv für Ohrenheilkunde*) of perforation of the mastoid process, with drills or with gouges, I found that in twenty-three a chronic purulent inflammation of the middle ear, of not less than five years' duration, preceded the acute symptoms which induced Dr. Schwartz to perform the operation of perforating the mastoid process; and in thirteen of this number—or fifty-six and one-half per cent.—well-marked sclerosis of the middle and upper portions of the process was found. Of the remaining ten cases, there are four in which no mention whatever is made of the condition of the bone, and six in regard to which it is distinctly stated that there was no sclerosis. I found, furthermore, that out of five cases of my own, which were similar to Schwartz's twenty-three cases, there were four—or eighty per cent.—in which more or less pronounced sclerosis of the mastoid process was discovered at the time of the operation or on post-mortem examination. This evidence, it appears to me, corroborates the truth of the formula which I have given.

¹ In 1880 I published the statement that the existence of a sclerosed condition of the mastoid process may be assumed in the great majority of cases of chronic puru-

¹ Read before the Harlem Medical Association, New York.

which the patients, though presenting no gross lesions of heart, lungs, or nervous system, yet were very much debilitated, as for example in two cases narrated by Kappeller (*Deutsche Chirurgie*), of strangulated hernia, in several others by malignant disease. Others again have been caused indirectly by the ether, as we all know, by inhalation of vomited matters, usually during partial unconsciousness while recovering from the anæsthetic or from the filling up of the trachea by blood during operations about the mouth and fauces. To this list of accidents I might add that certain French observers¹ claim to have seen death caused by suffocative bronchitis induced by the inhalation in some cases of chloroform, in some, and more frequently, of ether.

There is one source of danger from the use of ether which has not yet, I believe, been generally recognized by the profession. I refer to the danger of congestion of the kidneys, and consequent suppression of urine in patients already subjects of chronic Bright's disease. The elaborate monographs of Turnbull, written in 1879, Duret ("Des Contreindications l'Anæsthesie"), 1880, and Kappeller in the *Deutsche Chirurgie*, 1881, make no mention of disease of the kidneys as a contra-indication to the use of sulphuric ether. Lyman, writing in 1881, says that "even sulphuric ether may prove fatal if the kidneys are seriously damaged, but does not go into the subject beyond this slight allusion.

Isolated cases, however, of death resulting, in the opinion of their reporters, from the irritant effects of ether on diseased kidneys have been recorded. It is my purpose in the present paper to present to the Society what information I have been able to obtain from the literature of the subject, and to endeavor to form some estimate of its importance.

The power of ether to cause temporary suppression of urine is illustrated very markedly in a case reported by Mr. Lawson Tait, in the *British Medical Journal* of 1880 (vol. ii., p. 845), in which a fistula existed between the cervix uteri and one of the ureters. A constant dribbling of urine occurred from the opening. On two trials the urine ceased to flow as soon as the woman was etherized. As the stream of urine was essential as a guide in the performance of the operation, it had to be performed without an anæsthetic. There is no record of any urinary examination.²

The first to call attention to the danger of suppression of urine and death, resulting from the use of ether in cases of chronic Bright's disease, was Dr. T. A. Emmet, who, about sixteen years ago, made an opening into the bladder of a patient suffering from chronic cystitis, under ether. No water was passed after its use, and the patient died of uræmia three days afterward. Marked chronic lesions of the kidneys was found post-mortem. The case was published at the time in one of the Southern journals, and an abstract of it can be found in his work on gynecology. Since that time he says, in the same work, that he has seen "at least five cases, in public and private practice," of death occurring under similar circumstances. So strongly has Dr. Emmet been impressed by his experience that he considers albuminuria the contra-indication par excellence against the use of ether, and in such cases operates with the patient under the influence of opium and without anæsthesia. Dr. Emmet, in a personal communication, informed me that he had reported each case as it occurred at the meetings of the Obstetrical Society of this city, but I have been able to find only one of them in print. In that case pyelitis and advanced chronic interstitial nephritis existed.

Dr. William Hunt, in the *Philadelphia Medical Times* of January 9, 1875, reports a case of death occurring two weeks after an amputation of the thigh, in a patient whose pulse dropped dangerously at the time of the operation,

after a few whiffs of ether had been taken. The patient had fever, which was not pyæmic, but never had any uræmic symptoms. Dr. Hunt asks the question, "Had the kidneys anything to do with it?"

Dr. Sims, in his article on a death from bromide of ethyl, in *THE MEDICAL RECORD*, vol. xvii., casually referred to two deaths from suppression of urine in cases similar to Dr. Emmet's.

Dr. Hutchinson, in the *British Medical Journal* for March, 1879, reports the death of a feeble old man, eighty-four years of age, who was operated on for carcinoma of the lymphatics of the neck, who never became completely conscious after ether narcosis, became completely comatose in eight, and died in forty hours after cessation of administration of the anæsthetic. There had been no great loss of blood. The right arm seemed paralyzed. Tremor, passing into convulsions of the right side of the face occurred, and, later, tremor of the right arm. Contracted kidneys and an old cyst, dating back, probably, to an apoplexy ten years previous, were found post-mortem. Thorax not examined. No allusion to the possible connection of the kidneys with the result is made by the reporter. The prolonged coma and the convulsive seizure, however, suggest such a connection.

Dr. W. F. Norris, in a paper read before the American Ophthalmological Society in 1881, gives the history of two of his patients, whose death he attributes to the irritant effect of ether on the already diseased kidneys. The first was a child five months old, probably syphilitic, who was operated on by discission for cataract. Four hours after the administration of ether the child had convulsions, became comatose, and died. The kidneys were found to be fatty and intensely congested. The second case was that of a woman sixty-eight years of age, apparently in good health. Operation was the extraction of a cataract. After the operation there was some fever, thirst, and disturbance of digestion. She became delirious on the sixteenth, and died on the eighteenth day. The kidneys were found to be congested. There was increase of their fibrous tissue and fatty degeneration of the renal epithelium. Numerous casts were observed *in situ*.

These cases constitute all that I have been able to find in the literature of the subject. In reviewing them, the question suggests itself—Was the ether really the cause of the fatal exacerbation of the kidney diseases which killed the patients? The cases of Drs. Sims and Emmet were all operations on the female genito-urinary organs. It is a well-known fact that surgical interference with these organs may give rise to suppression of urine by reflex influence upon the kidneys, though it is my impression that such a result is more apt to occur in the male than in the female. The answer that may be given to this objection is, that both the reporters are men of large experience in gynecological operations, and that Dr. Emmet's statements on the subject imply—although he does not make any direct statement to that effect—that he has not met with any corresponding accidents when he has operated *without* ether. His strong conviction on the subject is certainly entitled to great weight.

Dr. Hutchinson's case, again, occurring in an old, much-exhausted man, might well be attributed to the general depressing effect of the ether on a broken-down constitution. The convulsive seizure, however, strengthens the supposition that uræmia had something to do with the result. This case suggests a way in which ether might prove indirectly fatal in cases particularly of the form of disease, *i.e.*, contracted kidney, from which this patient suffered. It is well known that the high arterial tension which accompanies this disease calls upon the heart for extra exertion, which results in the hypertrophy of that organ. As long as the heart can respond to the demands upon it, the high pressure in the kidneys enables them to perform their functions satisfactorily, even when very much diseased. If, now, the ether depresses the heart's action, a corresponding diminution of the exertion

¹ Richet: Gazette des Hôpitaux, July 12, 1879. Revillout: Gazette des Hôpitaux, No. liii., pp. 633, 635, 1879.

² Since the above was written Mr. Tait, in the *Lancet* for January 6, 1883, p. 39, states that in every case of vesico-vaginal fistula in which he has operated since the above recorded operation he has "observed the same thing."

from the kidneys must result, independent of the direct irritant effect of the agent on these organs themselves.

The case of Dr. Norris' child, in which death followed four hours after the use of ether, with symptoms distinctly pointing to uræmia and after a comparatively trivial operation, seems to me to be the most conclusive of the series, though the child must be supposed to have been on the brink of a spontaneous outbreak for the fatal event to have followed in so short a time. Another matter must be considered in this connection, and that is the recognized fact that the mere shock of the operation is apt to prove a grave matter for people suffering from Bright's disease. In reference to this subject Sir James Paget says, in his "Clinical Lectures and Essays:—" "I do not know by how many times the risks of a given operation are increased in any patient who has albuminuria, but I do know that you will find it safe never to perform any operation without an acquaintance with the manner in which the patient's kidneys discharge their function, and never to perform one, except under something like compulsion on a patient whose urine is constantly albuminous. I do not say that you should never operate on such a patient, for the exigencies of the local disease may justify you, as they may justify you in operating in advanced phthisis; but be clear that you operate against heavy odds; for even if the patient do not die with erysipelas or pyæmia, or some other form of diseased blood, he will be apt to linger with a wound half healed, till at last he dies of his renal disease, just as if you had done nothing for him." The suggestion conveyed in this quotation is applicable especially to the cases reported by Drs. Hunt and Norris, in the former of which death occurred in sixteen, in the latter in eighteen days after the operation. The depressing effect of an operation, it must be remembered, depends not a little on the morale of the patient. A cataract operation in a nervous female might be quite as serious as a much graver operation in a phlegmatic male. Dr. Norris recognizes this objection to the second case and reports one almost similar, in which death followed a cataract operation, with the important exception, that no anæsthetic was used. On the other hand, the reflection suggests itself that some of the cases on which Sir James Paget bases his estimate of the unfavorable influence of Bright's disease on the results of operations, may have been cases in which the *anæsthetic* was to blame and not the operation. The suppression of urine in the only two cases of Dr. Emmet's, of which I have been able to find any detail, resulted fatally in one case thirty-two hours, in the other three days after the operation. It is certainly possible that many such cases may have occurred and the operator may have failed to recognize any causal connection between the ether and the fatal result.

That ether has been employed frequently in cases of Bright's disease *without* bad results is certain. Dr. Norris in his paper mentions two cases, one of which had been anæsthetized twice, and the other three times by ether without obvious ill effect. Dr. T. G. Morton, in discussing Dr. Hunt's case in connection with a death from ether in his own practice (*American Journal of the Medical Sciences*, October, 1876), states that he has frequently given ether in cases of albuminuria without accident. The same is probably true of every surgeon of large experience. It is not to be denied that the recorded experience which I have been able to find on the subject is not entirely conclusive. Nevertheless, I think that the evidence renders it highly probable that structural disease of the kidneys furnishes a grave contra-indication to the administration of ether. Further experience is necessary before any approximate estimate of its gravity can be made. The frequent immunity from accident may justify the employment of ether in such cases under certain circumstances, but the surgeon certainly ought to be aware of the risk to which he is subjecting his patient, and ought to be sure that the advantages to be gained by the use of the anæsthetic more than counterbalance its dangers.

REMARKS ON CARDIAC ASPIRATION.

By F. M. CORWIN, M.D.,

NEW YORK.

THE subject of cardiac aspiration having recently attracted some attention and comment in THE MEDICAL RECORD, perhaps the following account of a case which came under my observation may be of interest to some of your readers:

The patient, a man aged forty, a native of Turkey, was admitted to Bellevue Hospital, November 2, 1881, in the service of Dr. Janeway, Dr. W. C. Stone being House Physician. Owing to his limited knowledge of English no history was obtainable. He had a very badly deformed chest, due to right lateral curvature of the spine. On admission he was much cyanosed, the face, lips, and hands being very blue. His respirations were increased in frequency and labored in character.

His pulse was about 120 a minute, of fair strength but irregular. There was considerable œdema of the lower extremities.

Physical examination of the chest gave no evidences of consolidation of lung. There were numerous subcrepitant râles and pleuritic crepitations all over both lungs. Voice-sounds not sensibly altered.

The heart was pushed upward, the apex-beat being an inch or more above the left nipple, and the impulse diffused. There was thought to be considerable enlargement of the heart, but owing to the misshapen chest and displacement of viscera, that point could hardly be determined with accuracy. The heart-sounds were distinct, and there was no murmur.

He was ordered whiskey and digitalis every two hours with milk diet. He got some sleep through the night; but on November 3d he was still much cyanosed, and if anything changed, he was weaker than on admission. His urine was found to be scanty, specific gravity 1015, reaction acid, and to contain about ten per cent. albumen, with large and small fatty and hyaline casts. Infusion of digitalis was substituted for the tincture.

About 3 P.M. of this day he was seen by Dr. Janeway, and the question of hydropericardium being raised, the needle of a veterinary hypodermic syringe was introduced at a point where there was dulness on percussion, and but little or no motion apparent on palpation. On withdrawing the piston, the barrel of the syringe, which held nearly an ounce, was immediately filled with dark venous blood, and as the needle had been moved slightly while in the chest, it was thought the heart had been penetrated.

There was no change in the condition of the patient at the time, nor did he afterward develop any symptoms or physical signs which could be referred to the aspiration. After this a considerable diaphoresis was brought on by surrounding the patient in bed with hot bottles wrapped in clothes wrung out of hot water, aided by spirits of mindererus and nitre. The cyanosis remained the same.

On November 4th, it was apparent that he was gradually growing weaker, otherwise there was no change. Stimulants were increased during the day, but he continued to fail, and died quietly about 8 P.M., death apparently being due to exhaustion.

Autopsy, November 5th, 3 P.M.—Heart weighed fourteen ounces, the increase in weight being chiefly due to hypertrophy of walls of right ventricle, the cavity of which was much dilated. About an inch from the apex of the right ventricle was a small ecchymosis, evidently where the needle had entered. There was no evidence of inflammation around it, or in the heart muscle, the ecchymosis being subserous only and not traceable into the muscle. The valves were normal. The pericardium contained some reddish serum, as did the peritoneum, and both pleuræ. There were no coagula in the pericardium, and no appreciable difference between the fluid there and that in the other serous cavities.

The lungs were very small, the lower portions especially being compressed and in a condition of atelectasis. The remaining portions were cedematous, and the small bronchi contained some mucus. There were numerous and strong pleural adhesions. Kidneys were much congested and the seat of considerable parenchymatous change. Capsules were adherent. All the other viscera were markedly congested, and cellular tissue of dependent portions of body was cedematous. On examining the interior of the thorax after removing viscera, the right side was found to be much infringed upon, the left side being much the more capacious. Owing to nearness of sternal ends of right ribs to spinal column, the liver was displaced upward and to the left, the left lobe pushing the heart well up. The right side dilatation and hypertrophy of heart was thought to have been due to obstructed pulmonic circulation brought about by the condition of the lungs.

It was the opinion of those present at the autopsy that the aspiration had not crippled or injured the heart in any way.

During my house-service I saw and performed cardiac aspiration a number of times, where the patient was moribund or the heart had ceased to beat, but I never saw any benefit resulting from it. I have narrated the above case somewhat in detail, as I believe it shows right ventricular aspiration to be practicable, in some circumstances at least, if anything is to be gained by it.

Reports of Hospitals.

THE ANTISEPTIC METHOD IN THE LONDON HOSPITALS.

(Continued from p. 238.)

(As reported by our London Correspondent.)

LONDON, January 22, 1883.

It is to the antiseptic methods as practised in the hospitals of London that we now address ourselves, and in order to do so it is necessary to revert to what has already been said, that few London surgeons have taken the trouble to follow even once or twice the practice of Mr. Lister in his own wards. As a consequence, there are many now practising and even teaching surgery in London who in all good faith profess to treat their patients "*à la Lister*." That such persons have every desire to do justice to their patients and to the system is not to be doubted, but from lack of confident belief in or knowledge of the minor details, these are neglected, and the result is disappointing. For example: we have seen a surgeon in a well-known hospital stand in the way of the spray for several minutes together, call for an instrument from the cupboard, and, without washing it in lotion, plunge it into the wound and use it for the remainder of the operation. Such a detail seems trivial in itself, and may possibly lead to no bad result, because the antiseptic material in the wound may be sufficient to destroy anything conveyed on the unclean instrument; but the point to be noticed is that this system must not be hastily blamed if carried out in an ignorant and incompetent manner. Again, there are others in London at the present moment who show a sort of unwilling allegiance to the system by treating certain classes of injuries and operations by all the complete details, while in other cases they will follow a nondescript antiseptic treatment, in some cases using one form of dressing and in some another, but always allowing the necessity of its being antiseptic. It is certainly a noticeable feature in Mr. Lister's career that neither argument nor obloquy has turned him aside from the strict observation of his own results, and though he has and still does occasionally make slight changes and modifications of the details of his method, yet this is done in strict accordance with the principle maintained, and one detail is only discarded

because another, which seems to promise better results, can be substituted in its stead. Of all the details of his method, the one which he is most ready to discard as not absolutely essential is the use of the spray; for it may be safely said that the danger of organisms entering by the air is the least of all those which are likely to arise in an operation, and if they do obtain access, they can be destroyed by washing the wound with an antiseptic lotion; and it must be remembered that for many years Mr. Lister worked without the spray and obtained good results, and the results which have been published by the late Mr. Callender, at St. Bartholomew's Hospital in London, and by Wendlenberg in Germany, show that the spray is not the most vitally essential element in the system; but, on the other hand, there is the fact that the author of the system is unwilling to relinquish its use, and this doubtless from the fact that he expects less immunity from danger by any other plan.

To answer the question, therefore, as to what have been the results of the antiseptic system on the surgery practised in London hospitals, two facts must be regarded. First, the question of general results, and, secondly, that of new operations which have been rendered justifiable by reason of the greater immunity which attends them. The first is really the smaller question, and is most easily and satisfactorily answered. There can be no doubt that the mortality from operations and from injuries has become, in a very considerable degree, diminished. Pyæmia, erysipelas, diffuse cellulitis, which a few years ago were only too rife in all our hospitals, are rare, and daily are becoming more scarce. Speaking of one of the largest, most wealthy, and best conducted hospitals in the metropolis, situated in the most open and healthy part of London, we can remember that fifteen or even less years ago pyæmia and erysipelas were rarely absent from the wards, while at the present time they are so seldom seen that their occurrence is a matter of surprise and consternation among the authorities. Not that in this institution the practice of aseptic surgery is by any one individual strictly carried out, but the teaching of Mr. Lister's principles has had such an effect in causing attention to be paid to details and to the necessity of some antiseptic precautions being taken in regard to every wound that the cases of septic poisoning are reduced to a very small number—a number which is capable of still further diminution.

With regard to the second, it must be remembered that many operations have of late years been introduced into practice which before antiseptic surgery was carried out would have been condemned as unjustifiable. Such, for instance, are the operations for the correction of deformities of the long bones of the limbs, or the many expedients which have been resorted to for remedying the defects in germ valgum, not to mention the very numerous procedures in which the abdominal cavity has during the last few years been opened. In all these operations the spray and antiseptic treatment are almost generally used by London surgeons with a very few exceptions, and this fact is a silent but important tribute to the extra amount of safety which it is considered is given by this method. In the operation for curved tibiae, for example, a large number of cases have been treated during the last few years, with only one fatality, at the Children's Hospital, while as a contrast between the present and the past it is curious and interesting to reflect that the operation had been occasionally performed in former years by one of the surgeons, but had been desisted from on account of the risk and danger to the patient.

Again, in abdominal surgery, the Master of Ovariectomy, Mr. Spencer Wells, has given the strongest testimony in favor of the aseptic treatment, and has shown that since adopting it his results have eclipsed all that preceded. His successor, Mr. Thornton, at the Samaritan Hospital, was a pupil of Mr. Lister's in Edinburgh, and is naturally a firm believer in his doctrines, though it must in justice be stated that his colleague, Dr. Bantock, has obtained

very satisfactory results by a course which discards the spray and the form of dressing recommended by Mr. Lister.

Mr. Savory, of St. Bartholomew's Hospital, is no convert to the aseptic treatment, and his views were ably and eloquently expressed in the meeting of the British Medical Association held at Cork three years ago. He endeavored to show that by cleanliness alone the results obtained at the hospital to which he is the senior surgeon were as good as could be claimed by the advocates of the antiseptic theory. Among the deaths, however, which took place according to the report published by the Surgical Registrar for the year following this address—namely, 1880—there were 45 deaths occurring after 619 operations, large and small (74 were for phimosi and 25 were tenotomies). Of these 9 were caused by pyemia and 4 from erysipelas, and this in a hospital with the most favorable surroundings which can be given by a liberal administration with an almost boundless fund at its disposal.

The practice of the other surgeons at this the largest of our metropolitan hospitals and schools varies somewhat according to the circumstances of the case. While some are careful and thorough followers of the system under discussion, others use it only in the more severe and perilous cases. Mr. Mornas Smith is one of the latter category, using it in all operations on the abdomen or upon joints, while he has of late used all the other many antiseptics which have been advocated in the treatment of ordinary cases and wounds of minor danger and importance. The principal of these are eucalyptus oil, carbolyzed wool, iodoform, and wool saturated with this material, boroglyceride, and many others. This latter agent has been used for some time at St. Bartholomew's, and was advocated during the past year by a surgeon to another hospital in one of his medical papers, on the strength of some half dozen cases which had done well under its use. We have, however, seen at least one fatal case of erysipelas occurring when this form of dressing was used after amputation of the breast, and are disposed to think less well of it than of many other materials which are in use for the same purpose.

St. George's Hospital, the school of Brodie and Hunter, is perhaps the most conservative of all as regards its treatment of surgical cases, but that an improvement is capable of being effected in the results of amputations is shown by statistics published by Mr. Holmes in 1874, which analyzed the last five hundred cases of amputation and showed a mortality of 158, or 31 per cent. The last two hundred amputations which were performed between the years 1866 and 1874—the years during which Mr. Lister's treatment was under discussion—75, or 37.6 per cent., ended fatally. With the exception of Mr. Holmes, who has discarded the general use of the aseptic system except in operations upon joints and others involving serious risk, no one at this hospital follows systematically the treatment under discussion. On the other hand, some attempts have here been made to improve upon the materials used, and with this object sulphurous acid spray was tried, but the results were not encouraging. Speaking generally of the treatment followed here, it may be said that antiseptic lotions are freely used, principally carbolic, and wounds are dressed either with gauze and protective or with carbolyzed wool, but as the surgical reports have not been published, no conclusion can be arrived at as to any improvement in results obtained.

One prominent London surgeon, Mr. Jonathan Hutchinson, of the London Hospital, has continued a line of treatment of his own, and has not been carried away into any deviation from it by the many more recently advocated. The wound, after hemorrhage has been arrested, is washed out with pure spirit; drainage-tubes are then arranged at the most dependent part and the wound is stitched up. Thin compresses, soaked in a lotion composed of six parts of absolute alcohol, a half part of liquor

plumbi, and sixteen parts of distilled water, are then applied, and are kept moist by an irrigator. Thus by using per drainage he follows the principle of Mr. Lister, but differs from him in abolishing the use of the spray and in substituting a different lotion, which is, by virtue of the alcohol, a distinct and satisfactory antiseptic.

It is difficult and indeed almost impossible at the present moment, when the opinions of surgeons are so greatly at variance, and are undergoing so great a reaction from those held and taught but a few years ago, to describe and individualize the treatment followed by different persons at the more prominent institutions in London, but it is not invidious to state that what may be seen in London hospitals is a fair interpretation of the general views of surgeons throughout this country, and a sketch has already been given of the extent to which the exact acceptance of the antiseptic treatment of wounds has been received. At every hospital there are one or more who have given it every chance which faithful observance and careful following can require, and the fact that their seniors and colleagues are willing to follow it in those critical and severe operations on parts in which septic poisoning is most to be anticipated does not weigh against it, but inclines, on the contrary, to show an unwilling acceptance of its value. The dangers and inconveniences attending the use of carbolic acid as a lotion have been shown to be due to a want of properly appreciating the way in which it should be applied; for it must be carefully remembered that the use of the protective is solely to avoid the contact of carbolic acid with the wound, and that where any antiseptic is used upon an open surface some other material which is proved innocuous has to be employed, such, for instance, as salicylic acid, boracic acid, etc. Among other materials which have not been already mentioned in the present article as having had their fair trial are eucalyptus oil, which has been used as spray as well as for a dressing, salicylic wool and jute, thymol, and many others.

What, then, we may well ask, are the results of this new doctrine as affecting the treatment now pursued in London, when compared with that followed by surgeons before its introduction some twelve or fifteen years ago? Firstly, the answer comes, a very greatly improved rate of mortality in all severer cases of operative and accidental wounds, and secondly a very widely extended field, which is daily on the increase, of operative measures, since they can now be undertaken with so much greater an immunity from disaster. The surgical records of our hospitals, the medical press, and the transactions of the various societies tell daily of recoveries from accidents and injuries which we were taught to regard in former years as inevitably fatal, and record operations of which our predecessors never dreamt of even proposing, but which are now performed with a percentage of mortality which is truly astonishing.

One collateral reason for this improvement is, no doubt, the better understanding of and the stricter attention to the hygienic surroundings of our patients, and another is the very great improvement in the class and education of our nurses. But, these apart, the details of surgical treatment are the main factors in the advance of the science, and of these none is of greater importance and none has done more to improve results than the appreciation and use of drainage. Whatever be the means resorted to of dressing wounds, almost every surgeon now looks to the careful drainage of all cases in which there is a possibility for the collection of any fluids, whether he uses india-rubber tubing, horse-hair, catgut, or decalcified bone. A stricter attention to cleanliness is also universally practised, both in the cleansing of the wound itself, usually by some antiseptic, and of all that comes in contact with it, such as the hands, the sponges, and the instruments. Then, too, in some form or other, antiseptic dressings are almost invariably applied, and this, with the use of drainage, necessitates a less frequent disturbance of the wound, which alone is of powerful influence in promoting its

speedy union. These means permit also of the more close approximation of the surfaces, and by securing their absolute rest and freedom from disturbance, allow nature more opportunity for performing her share of the work.

It will be seen, then, that we have in the above endeavored to show some of the influences which are at work in London, and in England generally, to improve the results of surgery. The progress in the last few years has been of marvellous rapidity, and it still continues to advance, but this is not an unfitting time to review the past with the present, and some ideas on the subject are, it is confidently hoped, set forth in the pages of this article.

Progress of Medical Science.

THE USELESSNESS OF STYPTICS.—In a paper read before the Philadelphia County Medical Society, Dr. J. B. Roberts (*Philadelphia Medical Times*, January 27, 1883) argues with much force against the use of styptics in general surgical practice. He states his objections to their employment in the following propositions: 1. Their reputation as hæmostatic agents leads practitioners to resort to them when more trustworthy methods are needed. Thus valuable time is lost, for, after temporary arrest, the hemorrhage recurs in the already anæmic patient, and is perhaps followed by disastrous results. 2. If they fail to control the bleeding—which they generally do if the hemorrhage is important—it is often so difficult to rid the surface of the pasty clots that subsequent ligation of the vessels is well-nigh impracticable. 3. Many styptics prevent union by first intention, because they irritate the raw surface, lead to inflammation, or induce suppuration.

He says, further, that Monsel's salt—the subsulphate of iron—has probably more reputation than any other styptic, yet it is the most objectionable of all. It covers the wound with black, sticky clots, which obscure further examination of the surface, prevent primary union, and may even allow bleeding to occur beneath them. I have seen such leathery masses of coagulum raised up into vesicles by the subjacent hemorrhage.

There are but two scientific and satisfactory ways of arresting hemorrhage as usually observed in the practice of general surgery: 1. The first is occlusion of each individual vessel by ligation, torsion, or acupressure, and is generally not required for arteries smaller than the facial, nor for veins, except those of the largest calibre. 2. The second method is direct pressure by compresses and bandages, which, if properly applied, will always be effectual when the first method is not demanded. It is to be adopted when there is oozing from small arteries and capillaries.

In all cases of traumatic hemorrhage, it should be recollected that a man can lose many fluidounces of blood without serious injury, and also that no artery or vein can bleed if it is compressed by the fingers. These facts assure the surgeon that there are always time and means to control the bleeding, at least temporarily. Many arteries that spurt freely when first divided soon spontaneously stop bleeding. Therefore it is foolish to interrupt the steps of an operation by ligating every little vessel that throws out a jet of blood. Let the surgeon proceed, even if the arteries are quite large, and when he has finished his incisions he will find, to his surprise, very few points requiring ligatures. He should ligate these, and, after washing away the loose clots, make moderate and equable pressure. There will then be no part for styptics to play. It is possible, perhaps, that there may be occasional instances of oozing where pressure cannot be effectually applied; but these are certainly so rare that they do not materially affect the truth of the proposition that styptics are useless.

THE USE OF THE MULLEIN PLANT IN THE TREATMENT OF PULMONARY CONSUMPTION.—Dr. Quinlan, of Dublin, observes that from time immemorial the verbas-cum thapsus, or great mullein, has been a trusted popular remedy in Ireland for the treatment of phthisis. After relating some cases where it proved of benefit, he concludes: "These cases although too few to justify any general conclusion, appear to establish some useful facts. The mullein plant boiled in milk is liked by the patients: in watery infusion it is disagreeable, and the succus is still more so. The hot milk decoction causes a comfortable sensation, and when once patients take it they experience a physiological want, and when the supply was once or twice interrupted, complained much in consequence. That it eases phthisical cough there can be no doubt; in fact, some of the patients scarcely took their cough-mixtures at all—an unmixed boon to phthisical sufferers with delicate stomachs. Its power of checking phthisical looseness of the bowels was very marked, and experiment proved that this was not merely due to the well-known astringent properties of boiled milk. It also gave great relief to the dyspnoea. For phthisical night-sweats it is utterly useless: but these can be completely checked by the hypodermic use of from the one-eightieth to one-fiftieth of a grain of the atropia sulphate; the smaller dose, if it will answer, being preferable, as the larger causes dryness of the pharynx, and interferes with ocular accommodation.

"In advanced cases it does not prevent loss of weight, nor am I aware of anything that will, except koumiss. Dr. Carrick, in his interesting work on the koumiss treatment of Southern Russia (page 213) says: 'I have seen a consumptive invalid gain largely in weight, while the disease was making rapid progress in her lungs, and the evening temperature rarely fell below 101° Fahr. Until then I considered that an increase of weight in phthisis pulmonalis was a proof of the arrest of the malady.' If koumiss possesses this power, mullein clearly does not; but unfortunately, as real koumiss can be made from the milk of the mare only, and as it does not bear travelling, the consumptive invalid must go at least to Samara or Southern Russia. In pretubercular and early cases of pulmonary consumption, mullein appears to have a distinct weight-increasing power. In early cases, the mullein milk appears to act very much in the same manner as cod-liver oil; and when we consider that it is at once cheap and palatable, it is certainly worth a trial."—*British Medical Journal*, January 27, 1883.

INTERCURRENT PLEURISY IN HEART DISEASE.—Dr. Bacquoy has observed a number of cases of pleurisy occurring in the course of heart disease. He states that notwithstanding the weakened condition of the patients consequent upon the prolonged cardiac trouble frequently associated with albuminuria, the inflammation presents all the characteristics of subacute idiopathic pleurisy, and is entirely distinct from hydrothorax. It usually pursues a favorable course, ending after a variable duration in a cure with resorption of the effusion. The treatment should be that followed in ordinary pleurisy. It is, however, desirable that a cure be obtained as speedily as possible, because of the embarrassment of the already enfeebled heart by the pleuritic effusion. Consequently the author advises an early thoracentesis in all cases in which the absorption of the fluid is delayed. Especially should this be done if dyspnoea or other urgent cardiac symptoms be present.—*La France Médicale*, November 30, 1882.

UTERINE MOVEMENTS.—In formulating the results of a large number of experiments made upon rabbits, Dr. Frommel states that the uterus undergoes regular rhythmic contractions. These contractions occur in all stages of uterine development, though they are more regular in pregnant animals or in those which have previously borne young. The movements are slowed by a low temperature, and quickened by a slightly increased

one; but a high temperature (103° F. or more) abolishes them. Circulatory disturbances exert a marked influence upon the contractions. Compression of the aorta causes them to cease within a very short time; that of the vena cava produces the same effect after a longer period (fifteen to thirty minutes). The author states that the uterine contractions are independent of any nervous centre situated without the organ itself, though, of course, they may be modified by impulses received from the cerebro-spinal centres.—*Centralblatt für Gynäkologie*, November 25, 1882.

EXTIRPATION OF THE GALL-BLADDER.—Dr. Carl Langenbuch reports the following case in the *Berliner Klinische Wochenschrift* of November 27, 1882: A man, forty-three years of age, had been suffering for six years with repeated attacks of bilious colic. They recurred with increasing frequency until, at the time of the patient coming under observation, they came on usually twice a day. The pain was intense, and increasing doses of morphine were taken to relieve it. The patient was emaciated and weak, had no appetite, and suffered from constipation and constant nausea. It was determined to remove the gall-bladder. A T-shaped incision was made at the outer border of the rectus muscle, and the cystic duct was first ligated. The bile was then withdrawn by aspiration, and the gall-bladder removed. On the morning following the operation the patient was found sitting up in bed smoking a cigar. He went on steadily to recovery, complaining of nothing but a ravenous hunger, and in twelve days left his bed. In six weeks the patient gained thirty pounds in weight. Four months later he reported himself entirely free from pain, in excellent general health, and completely cured of the morphine habit which had been acquired during the last year of his sufferings.

INFLUENCE OF CONTINUOUS COLD UPON THE DEEPER TISSUES.—Dr. Bayer formulates the following conclusions from an elaborate series of experiments made upon dogs: 1. Local abstraction of heat causes a cooling of the neighboring and underlying organs and tissues. 2. The lowering of the temperature of a part is less marked the more distant it is from the cooled surface. 3. The heat-losing property of a given tissue is in inverse proportion to its vascularity. 4. The local cooling announces itself by a more speedy fall of the general temperature. As a practical application of his researches, he states that ice-water should not be used as a hæmodynamic, since the contraction of the vessels depends upon a continuous application of a moderate degree of cold rather than upon that of a very low degree. He does not, however, deny the efficacy of ice applications in bruises and subcutaneous injuries; but he states that in these cases the deeper tissues do not attain the same degree of cold as when ice is applied directly to the bleeding vessels. They receive only the proper degree of continuous cold to insure the contraction of the blood-vessels. The value of local cold applications in inflammations is thus explained: The direct cooling of the tissues depresses their activity. The vessels being contracted, the migration of white corpuscles is restricted, the general temperature is lowered, and the heat centre is depressed by reflex influence.—*Zeitschrift für Heilkunde*, November 15, 1882.

PARASITES IN AMERICAN PORK.—From an investigation into the parasites in the pork-supply of Montreal, Dr. Osler concludes: 1. That the hogs slaughtered for our markets present parasites in numbers sufficient to necessitate a more thorough inspection than is at present carried out. 2. As regards *trichina spiralis*, which was found in the proportion of 1 to 250, he is of opinion that, considering the extreme rarity of cases of trichinosis, and the difficulties attendant upon a systematic inspection, a compulsory microscopic examination of the flesh of every hog killed is not at present called for. 3. In the case of "measles," the liver should be carefully examined, and

if present in it, the flesh of the animal should receive the special attention of the inspector; if only in the liver, the entire carcass need not be confiscated. 4. Echinococcus cysts in the liver render that organ unfit for food, but in other parts, unless very numerous and disorganizing, they may be cut out, and the carcass remain marketable. 5. The public should be made aware of the possible dangers of eating, in any form, raw or partially cooked meat. The best safeguard against parasitic affections is not so much inspection of the flesh, unless, indeed, this is minutely carried out, as careful attention to culinary details. 6. To reduce the number of infected hogs, greater attention should be paid to their hygienic surroundings, particularly in the matter of feeding. The danger is not during the period when the animals are penned and fed on grain, etc., but when they are allowed to roam at large and feed indiscriminately.

TREATMENT OF BUBO.—Dr. Hermann Kümmell employs a dressing of bichloride of mercury after the extirpation of an inguinal bubo. He removes the whole group of glands, and not merely those that are affected. After the extirpation of the glands the wound is thoroughly dried with sponges, drainage-tubes being inserted into the deeper pockets, if necessary. The edges of the wound are then approximated by sutures, except for a short space at the lower edge, which is left open for drainage. The surface over the wound cavity is now covered with pads of gauze soaked in a bichloride solution, or with little ash bags, one or two larger bags being placed over all. Firm pressure is then made with a roller bandage. After eight or ten days the dressing is removed and a second one applied, if necessary. Disturbance of the wound by flexion of the thigh is prevented by a short splint extending from the anterior superior spine of the ilium to the middle third of the thigh. Where an ulcer has already formed, the infiltrated parts are removed by the scissors and the sharp spoon, and the cavity is filled with sand wet with a solution of the bichloride, and covered with a few layers of gauze. Should the discharge be sufficient to saturate the outside dressing, this is removed and fresh gauze applied. The sand, however, is not removed, but is wet again with the solution. Dr. Kümmell claims excellent results in the treatment of bubo by this method. In cases where the skin is still sound, he says that union by first intention is usually obtained, and where ulceration has occurred, the wound heals rapidly by granulation with a very moderate amount of suppuration.—*Centralblatt für Chirurgie*, December 30, 1882.

HYPERIDROSIS OF THE AXILLA IN THE NUDE SUBJECT.—Dr. Aubert reaches the following conclusions (*Annales de Dermatologie et de Syphiligraphie*, December 25, 1882), from a study of this phenomenon in a large number of individuals: 1. Axillary hyperidrosis is almost always present in nude subjects. 2. This is so great in many instances that streams of perspiration may be observed running down the body and inner side of the arm. 3. The chief cause of this phenomenon seems to lie in the anatomical disposition of this region permitting of a local elevation of temperature, while that of the general surface is lowered by the surrounding atmosphere. 4. This local elevation in a number of instances amounted to nearly 1° F. 5. Various facts lead to the supposition that this elevation of temperature finds in the glands of Robin an organ favorably disposed, by its innervation and structure, to the reception of thermic influences. 6. The mental effect produced by nudity and examination may aid in causing an increased secretion, but it plays a very subordinate rôle in the production of this phenomenon.

THE LEGAL RELATION BETWEEN DOCTOR AND PATIENT.—No binding agreement can be made between the patient and the doctor in Paris, as the patient is not regarded legally as a free agent.—*Detroit Lancet*.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, March 10, 1883.

THE INFLUENCE OF THE THEATRE UPON THE PUBLIC HEALTH.

As long ago as 1856 an elaborate essay upon the relations of the theatre to the public health was written by M. Bonnaire of Paris. The author was at the time justly criticised for his extravagant denunciations of play-houses, which, excepting the opera, he considered to be little better than pest-houses in their influence upon the human body. Since Bonnaire's day occasional comments have been made upon the subject, but it has hardly received the consideration which it deserves. Artistic and moral questions are those which the drama chiefly excites. Our attention has been called to the subject now, however, by a number of instances communicated to us, which show, if that were needed, that the theatre bears a relation of no inconsiderable importance to preventive medicine.

It is not the question of protection against fire, which especially concerns the sanitarian. Even the results of sitting for two or three hours in over-heated and ill-ventilated halls, or of passing from these, while thinly clad, into the open air, are of a minor importance and do not concern us now.

The influence of theatre-going upon the young and immature of our cities is a matter, however, which does claim thoughtful attention. We venture to state most positively that this influence is bad. With a nervous system still unformed and unstable, the excitement of the melodrama or tragedy, the late hours, the precocious ideas, the distorted and often false notions of life and character presented, all tend to act injuriously both upon mind and body. In the larger cities there is always among the better classes a great number of silly stage-struck girls, whose nervous system, already unstable, is made more so by a fondness for theatre-going, or a secretly nursed ambition to become actresses themselves. Occasionally these city maidens become affected with a passion for a particular artist, which develops into an epidemic. Witness the popularity of an actor, not long deceased, of only moderate abilities, but of more than ordinarily pleasing appearance. The abnormal devotion which he excited was strictly comparable, though less grotesquely accentuated, to the dancing epidemics of the middle ages. That such perversions and exaggerations of youthful emotion may excite hysteria, chorea, and a varied train of morbid nervous symptoms was the claim of M. Bonnaire, and may be in part allowed.

Among the humbler classes who attend the spectacular

and murderous melodramas, or the licentious variety shows which make up the programmes in cheaper resorts, similar pernicious effects follow. We do not speak of the moral side, but only of the physical. The premature excitement of the sexual passion, the unhealthy stimulus given to the emotions and the imagination react upon the body.

It is quite universally agreed that stimulants injure the young and immature in a special degree. Remembering that the drama is a psychical stimulant and often one of great intensity by very poor quality, parents and perhaps even the State should be called upon to be careful how indulgence in it is allowed.

THE CAUSE OF TISSUE-METAMORPHOSIS.

THERE are a good many pathological theories which have a certain intellectual value quite apart from any more solid merits. The ingenuity of argument and elaborate collation of facts often shown stimulate the attention, at least, and furnish, perhaps, a little useful mental discipline.

Professor Schmiedeberg has given to the medical world an ingenious hypothesis, regarding which the foregoing remarks are pertinent. This gentleman has been for some time industriously studying the nature of tissue metamorphosis, or, in the learned nosology of modern science, metabolism.

The process by which the changes of formed tissue (e.g., muscle, gland, nerve, etc.) into excrementitious products takes place has long been the object of scientific inquiry. Professor Schmiedeberg claims to furnish us with a part of the solution. He shows first of all that when certain aromatic bodies, like benzol, are mixed with alkaline fluids or blood, only a slight amount of oxygenation takes place. When, however, these substances mixed with blood are sent through an isolated gland like the kidney or the lung, oxygenation takes place nearly a thousandfold more actively. From this and other facts he concludes that the tissues have a special action on oxidizable substances, rendering them able to take up that element actively from the blood. It is right, therefore, to expect that certain substances can unite with oxygen in the blood very actively by virtue of the tissue action about them—which action may be attributed to a ferment.

The exact significance and luminousness of this discovery are not so very apparent. A further series of experiments, however, with nitrogenous substances resulted in a discovery which, if corroborated, has a much more practical bearing. The decompositions of nitrogenous bodies in the system are due, says our investigator, to the presence of an unformed or soluble ferment, which he calls "histozyme." This ferment he has separated from a glycerine extract of pig's kidney by precipitation with alcohol. It is assisted in its decomposing actions by the presence of the oxygen in the blood. As an example of its effect a solution of benzylamine in blood, passed through the kidney of a dog produced benzoic acid. Without the histozyme, this effect cannot be produced. The chemical change is thought to be as follows: the benzylamine is turned by the ferment into benzyl alcohol and ammonia, then the oxygen of the blood

unites with the former to make benzoic acid, while the carbonic acid unites with the ammonia to form urea.

The practical side of this supposed discovery lies in the relation of the histozyme to the production of fever. When a solution of it is injected in large quantities into a dog, it causes malaise and rise of temperature. Professor Schmiedeberg thinks that some febrile conditions are caused by an excess of the ferment in the body.

The relation of the ferment to such diseases as gout and rheumatism is naturally suggested.

Further experiments in substantiation of the claims for the histozyme are being made, and they are, we confess, much needed.

FORENSIC MEDICINE.

In an inaugural address recently delivered by Clark Bell, Esq., before the Medico-Legal Society, some interesting facts are given regarding the condition of medico-legal science in Europe and America. There are, we are told, only two scientific bodies in the world devoted entirely to the study and discussion of medico-legal topics. These are the Medico-Legal Society of France and that of New York. A third society is, however, soon to be organized in Italy, and a fourth has recently been organized in this city.

As to the general condition of forensic medicine, it appears that the existence or not of definite organizations is not a strict measure of scientific work in different countries. Great Britain, for example, although without a society or a journal, has had some eminent writers on forensic medicine, prominent among these being Woodman, Tidy, Guy, Taylor, Husband, and Winslow. Germany, also, as regards actual work, leads all other civilized countries, and indeed contributes as much as all others combined. Of a series of works on poisons, numbering 152, 100 were written by Germans, 33 by French, and 19 by English speaking authors. Among 498 other contributions to the science in question, 319 were by Germans. Of late years, however, the number of articles by French, English, and American authors has very greatly increased.

The importance of medico-legal knowledge is recognized much more fully in many European countries than it is in America. Chairs for its teaching exist in many, if not all of the medical colleges, and in some of the legal schools in Europe. France appears to be at present most active in discussing the science, and disseminating a knowledge of it by means of official bulletins, journals, volumes of transactions, and society discussions.

America has shown an increasing interest in medico-legal subjects. The Medico-Legal Society of Massachusetts, organized not long ago, consists chiefly of medical examiners appointed by the Governor under the new law abolishing coroners. This body, though it has not published officially any scientific contributions, is likely to give an impulse to forensic medicine.

There is, undoubtedly, all over the country a growing interest taken in questions relating to insanity and the commitment and care of the insane than ever before. The New York Medico-Legal Society has had an addition of nearly one hundred members during the past year. Its library has also been increased by the addition of 564 pamphlets and 376 volumes. The continued

growth of this society and the organization of others seems inevitable. For every doctor, whether specialist or not, is liable to be called upon the witness stand, and thus be forced into an active interest in some branch of forensic medicine.

The New York Society proposes several undertakings which are likely to prove of great value. One of these is the securing translation and publication of foreign medico-legal works; another is the inviting of all superintendents of hospitals, asylums, prisons, charitable institutions, municipal boards, judges, district-attorneys, and others to communicate to this Society cases involving medico-legal questions. This plan has been adopted with success in France. Lastly, it is proposed to publish a medico-legal journal, which shall be the organ of the Society and contain its papers and proceedings. As there is no journal devoted entirely to medico-legal science in the world, it is thought that such a publication would meet wide support in both the legal and medical profession.

THE PANCREAS IN FEVER.

It is well known that disturbances of the digestive secretions take place in fevers, and these changes, so far as the stomach and salivary glands are concerned, are tolerably well known. Dr. S. Stolnikow has recently made a series of investigations into the condition of the pancreas in fever, and his observations form a noteworthy contribution to the pathology of febrile conditions.

His experiments were made upon dogs with permanent artificial pancreatic fistulæ. It was first found that these animals, in normal condition, secreted from 27 to 30 c. ctm. of pancreatic juice in the first two hours after a meal; and that then the secretion fell to about 1 to 2 c. ctm. per hour. Artificial fever was then produced in nine dogs by injection of septic fluids, and in two cases by inclosing the animals in hot boxes. It was observed that regularly after the injection there was an enormous increase in the pancreatic secretion for about two hours, the amount being from 70 to 79 c. ctm. (about 5 iiss.) per hour; then a change took place. The secretion rapidly diminished, and finally completely ceased. It was found, therefore, that in fevers there is at first a short increase, then a complete stoppage of the secretion of the pancreatic gland. This stoppage was not influenced by the taking in of food. We are not told how long the fever and its attendant pancreatic disturbance was kept up. It is not likely, however, that, in a prolonged fever of many days, the pancreas continues entirely inactive, but only that the general effect of the febrile condition is to lessen very materially the activity of this gland, just as it does that of the parotid and those of the stomach.

Stolnikow made some experiments in order to determine the nervous mechanism of the phenomena in question. His conclusion was that the septic poison (and probably also the heat) acted first as a stimulant to the local nervous ganglia which excite secretion, and that it then paralyzed them. In this latter action it resembled atropine. Our investigator found that the ferments of the pancreas were present in the gland during fever, although they were not carried off in the secreted fluid. He also found that they were present in quite varying amounts, and

concludes from this that the manufacture of each of the three ferments is under a different nervous control.

The practical suggestion which he offers is that possibly pilocarpin may be given with benefit in fevers, on account of its stimulating properties upon the pancreas.

BEER AND INEBRIETY.

IN the January issue of the *Journal of Inebriety* is an editorial article which strongly protests against a prevalent view that beer and light wines may be safely substituted for the stronger alcohols. Many persons who believe in temperance, but not in teetotalism, have held the opinion that, in this country, the introduction of malt liquors and table wines would satisfy the demand for alcohol without causing a serious amount of disease and vice. This theory, we are now told, is without support in facts. In Germany, for example, the consumption of brandy and whiskey has been steadily increasing since 1837, and in 1881 it was double the amount per capita to that in England or the United States. There has been also an increased demand for strong drinks in France. In this country the use of beer has increased far beyond that of distilled liquors. We are not allowed to draw comfort from this fact, however, but are told that inebriety is increasing at a greater rate than the population, thus showing that beer has no apparent beneficence.

The statements of our contemporary deserve much attention. The facts given, however, are far too few to establish the point claimed. The increased demand for stronger alcohols is often due to the stress of modern life. Certainly, a community that drinks malt liquors is safer than one which depends on whiskey for its stimulus. It would be better without either, but humanity is frail, and we must study it as it is.

QUACKS IN NEW YORK AND LONDON.

THE *Medical Press and Circular* a short time ago made some comments upon our editorial regarding "Quackery in Missouri." Our contemporary first bemoaned the sad state of affairs in Missouri, then transferred its melancholy and disapprobation to the whole United States, including especially New York. The logical process in the sympathetic and cosmopolitan mind of our esteemed contemporary was as follows: Missouri is a quack-ridden State, therefore New York and all the United States are the victims of a pestilent and utterly utter charlatanism.

Now, we trust that it is not merely a narrow and local prejudice which makes us protest against these conclusions on the part of the *Press and Circular*. We think it should really be known, for instance, that Missouri is half a continent from New York geographically, is governed by different medical laws, and is under somewhat different social conditions. We make no unfair insinuations against Missouri, which is a robust commonwealth, and one that contains many eminent and representative physicians. But it really is a very different place from New York and many other States, so far as quackery is concerned. The New York law compels every practising physician to have a diploma, which diploma is always an evidence of some medical education at least. We cannot boast that our State has been so purified of char-

latany as Illinois, or that there are not other States whose medical status is as good or better. But we are quite sure that London has as many quacks as New York, where the registration law is sharply enforced, and that the wholesale charge that the United States is pitifully quack-ridden is quite untrue.

THE TENTH CENSUS AND THE PROFESSIONS.

THE "Compendium of the Tenth Census" furnishes some facts regarding the professions of our country.

The total number of physicians and surgeons in the United States in 1880 was 85,671, of whom 2,432 were women. The number of lawyers was 64,137, of whom 75 were women, and the number of clergymen was 64,698, of whom 165 were women.

The following table shows that of foreign countries Germany contributes most to our profession, England and then Ireland following. The clergy are mostly supplied from foreign sources, while medicine ranks next.

Profession.	United States.	Ireland.	Germany.	Great Brit. in.
Physicians.....	77,092	1,021	2,640	1,748
Lawyers.....	60,342	1,008	791	948
Clergymen.....	51,967	2,516	4,301	2,589

As Germany contributes about one-seventeenth of all gainful occupations, the number of German physicians is not disproportionately large. The same may be said of Ireland and Great Britain.

The facts for a study of the duration of working life in the different professions are given.

Profession.	Under sixty years of age.	Over sixty years of age.
Physicians.....	77,274	8,397
Clergymen.....	55,779	8,919
Lawyers.....	60,241	3,896
Dentists.....	11,880	434
Musicians.....	29,450	837
Artists.....	8,699	368
Authors, etc.....	1,006	124
Commercial.....	1,726,020	54,611
Agriculture.....	6,324,053	625,711

From the above table it will be seen that more clergymen survive their sixtieth year than any other professional men. Physicians rank next, and lawyers last, with quite a gap between them. The agricultural classes have nearly as good a life as physicians, while of those engaged in trade and transportation a very small proportion continues in activity after the sixtieth year. Artists of all kinds have a short working-life, a fact which is in harmony with the general law that those who subsist by cultivating impressions and emotions die earlier than real brain-workers.

SURGERY FOR ENGINEERS.

THE trustees of the University of Pennsylvania have engaged a lecturer on operative surgery, who is to give a course of lectures on operative surgery to the senior scientific class of the collegiate department of the University. The object is to give them sufficient surgical knowledge to enable them to deal with the accidents and emergencies which are frequent in the lives of civil and

mining engineers. It is an application of the methods adopted by the First Aid to the Injured societies. The class selected for instruction, however, is presumably an intelligent and educated one. It is, therefore, quite likely that some instruction in anatomy, physiology, and minor surgery will be very useful. We take no roseate views of the great advantages resulting from elementary surgical instruction to the laity. No one, so well as the practising physician, knows how rapidly a little technical knowledge is forgotten unless continually applied. But the project adopted by the Pennsylvania University is a simple one, and while doing no harm, may occasionally be productive of good.

News of the Week.

A PUBLIC SCHOOL MEDICAL SERVICE.—It is proposed in Paris that a medical service be formed for the purpose of ascertaining what chronic or constitutional diseases affect the teeth, eyes, or ears of the pupils in the public schools, and of devising suitable remedies for the ailments.

PROHIBITION OF PATENT MEDICINES IN ITALY.—By a law which has just come into operation in Italy, the sale of patent medicines throughout the kingdom is prohibited unless the precise composition of the medicine is stated. The promulgation of this important decree has been made by the Minister of the Interior, the Customs, and the sanitary authorities. One well-known chemist in Rome has at the present moment nearly five hundred dollars worth of patent medicines lying at the Dogana, and likely to have to remain there or to be sent back to England undelivered. For the future, travellers will have to smuggle their favorite drugs into Italy.

FIRE IN BELLEVUE HOSPITAL.—A temporary excitement was caused in Bellevue Hospital last week by the breaking out of a fire in Ward 7. A considerable part of the floor was burned, but the flames were soon extinguished without assistance from the Fire Department.

THE MANUFACTURE OF DRUGS AND CHEMICALS IN THE UNITED STATES involves a capital of \$28,598,458. Products to the value of twenty-eight millions are annually made.

In contrast to this legitimate work, the manufacture of patent medicine involves a capital of ten and a half millions, and produces mixtures valued at fourteen and a half millions annually.

The number of manufacturing establishments is five hundred and sixty-three.

THE MIAMI MEDICAL COLLEGE held its annual Commencement on March 1, 1883.

THE OHIO MEDICAL COLLEGE held its Commencement March 8, 1883.

THE CINCINNATI MEDICAL COLLEGE held its annual Commencement on February 27th.

DEFEATING MEDICAL REFORM.—The Legislature of Indiana recently defeated the Bowers bill to regulate the practice of medicine in that State by a vote of (in the House) 46 to 41.

THE BILL TO PREVENT THE IMPORTATION OF ADULTERATED TEAS was passed by Congress.

THE MEDICAL DEPARTMENT OF THE ARKANSAS INDUSTRIAL UNIVERSITY held its annual Commencement on February 28th, graduating a class of four, to whom there were distributed six prizes.

A FRENCH SOCIETY OF OPHTHALMOLOGISTS has just been organized in Paris. M. Chilret was elected President pro tem. The meetings are to be held annually in January. M. Gayet, of Lyons, opened the scientific work with a paper upon a rare form of cyst of the iris.

A MEMORIAL TO THE LATE PROFESSOR BUHL is to be erected in the Pathological Institute at Munich.

PHILADELPHIA'S STREETS.—New York does not suffer alone from filthy streets. The grand jury in Philadelphia calls attention to the very dirty and unhealthy condition of the streets of the city at the present time, and to the evil effects of not providing some other and easier outlets for the sewer-gas than the dwelling-houses of the citizens.

THE MEDICAL COLLEGE OF INDIANA held its annual commencement on March 1st, at English's Opera House, Indianapolis, graduating a class of fifty-three. Two prizes were given.

A MEDICAL JOURNAL SUPPRESSED.—*The Wiener Medicinische Blätter* has had the honor of being confiscated by the Austrian authorities on account of an article which appeared in it criticising the sanitary arrangements of the army.

LA VOX DE HIPPOCRATES is the ingenious title of a new medical journal recently started in Mexico. The voice of Hippocrates has been sounding down the ages but we hardly thought it would bring up in Mexico.

A PROTEST AGAINST THE INDISCRIMINATE USE OF POTASSIUM CHLORATE.—The Medical College of Hamburg has issued a protest against the too frequent use, without medical advice, among the laity of chlorate of potash.

THE WIDOW OF PIROGOFF has given the University of Moscow 12,000 roubles, the interest of which is to be applied to the endowment of two lectureships in the name of Pirogoff.

THE IMMIGRATION OF GERMAN PHYSICIANS is a thing which is yearly increasing, and which deserves some attention from the profession in America. They now number over two thousand, and they generally succeed abundantly. Such, at least, seems to be the opinion entertained among themselves. A German (or Russian) physician, practising in Chicago, has sent a letter to the *St. Petersburg Medicinische Wochenschrift*, in which he answers, as he says, a large number of inquiries that he is constantly receiving, as to the prospect which European physicians have, if they come over here. He says: "With the ordinarily slight practical education which American physicians possess, it is not so very difficult for European physicians to obtain a very good practice here." It is only necessary, he continues (1) that the European in question have some knowledge of English; (2) that he have some money to start with; (3) that he select the right location. The letter concludes with some more

detailed advice. It has already been copied and widely circulated by German medical journals. There is no doubt some truth in the fact that German physicians coming over here, thoroughly equipped medically, easily keep, at least, the practice among their countrymen.

It may be seriously questioned if they will not do much more if our colleges continue at their present low standard.

A WOMAN PHYSICIAN PRESIDENT OF A MEDICAL SOCIETY.—Dr. Jennie McCowan was elected President of the Scott County Medical Society, Iowa, on February 15th. This is, we believe, the first instance on record in which a woman has been elected to preside over a body of medical men.

THE AMERICAN VETERINARY COLLEGE held its Eighth Annual Commencement last week, and degrees were conferred upon twenty-eight graduates. Rev. Henry Ward Beecher delivered the address.

AN INTERNATIONAL QUININE QUARREL.—During the recent typhoid epidemic in Paris, a German firm in Milan supplied a Paris house with considerable quantities of sulphate of quinine for the hospitals. It was suddenly perceived that this sulphate, which cost 450 francs a kilogramme, was adulterated with a substance costing only 150 francs. The adulterated article was refused, and the French newspapers denounced German and Italian manufacturers as fraudulent. This caused a great sensation in Italy and Germany. The manager of the Milanese factory hastened to Paris, and it was discovered that it was the Paris house that had substituted the spurious substance for the real sulphate of quinine—a fact which the head of the Paris house himself admitted in a letter to the manager of the Lombard factory. The latter has now commenced an action against the Paris house; but, though the French papers, especially the *Temps*, have acknowledged their mistake, the papers of Germany and Italy continue to manifest great irritation at an accusation which might have thrown discredit on their respective chemical products.

CONGRESS AND THE NATIONAL BOARD OF HEALTH.—Congress has adjourned and the National Board of Health has only been remembered to the amount of \$10,000 for "compensation and personal expenses of its members."

The most earnest friends of the Board look upon this action by Congress as indicative of a desire to discontinue the Board as at present organized. What will be the outcome it is difficult to surmise, but some prominent medical men think that Congress will eventually clothe the various services already in existence with ample power to manage epidemic diseases, without the intervention of an outside organization. Others think that as quarantine matters are of the same nature as police matters, they should be left with the States or municipalities interested, and that the General Government has no more jurisdiction in the one case than in the other. This opinion is held by President Cabell, of the National Board of Health, who says: "I hold that any attempt to supersede State authority, in matters of quarantine, or for the General Government to exercise concurrent jurisdiction with the States in regard to quarantine would be inexpedient."

The whole profession will regret the loss of a national scientific organization, and we trust that one will again be established on a satisfactory basis. Meanwhile a Board which has \$10,000 a year should be able to do some profitable work.

Reviews and Notices.

THE HOSPITAL TREATMENT OF DISEASES OF THE HEART AND LUNGS, with over Three Hundred and Fifty Formulae and Prescriptions, as Exemplified in the Hospitals of New York City: Bellevue, Roosevelt, St. Luke's, New York, Presbyterian, German. Charity, St. Francis, Mt. Sinai, in the services of Drs. Alonzo Clark, Austin Flint, Alfred L. Loomis, E. G. Janeway, W. H. Draper, F. Delafield, W. H. Thomson, A. Jacobi, J. R. Leaming, A. H. Smith, Beverley Robinson, J. Lewis Smith, G. G. Wheelock, J. H. Ripley, F. H. Bosworth, A. C. Post, A. A. Smith, etc. By CHARLES H. GOODWIN, M.D. New York: C. H. Goodwin, M.D., 245 West Fifty-third Street. 1883.

THIS unpretentious little volume will prove of great service to those numerous practitioners who come to this city for the purpose of refreshing and enlarging their knowledge of disease and its treatment. Its possession will save them much valuable time which, they otherwise would have to spend in taking and copying notes on treatment and prescriptions, and which they will employ to greater advantage by the observation and examination of cases. This book will also be found to be of value to the young graduates just entering upon their duties as internes in the various hospitals of this city, as well as anywhere else. It reproduces, with photographic fidelity, the features of treatment, as actually carried out, and has the advantage over bulkier books on therapeutics that it does not enumerate long arrays of remedies from which it is difficult to make a choice.

In a work like this careful proof-reading is very important, and we are glad to state that though we have searched for errors with an unsparing eye, we could not detect any of importance, except on page 81, where one ounce of the syrup of senega is put down as an expectorant dose, and on page 153, where fifteen grains of chloral hydrate is stated to be the quantity given to "children" as a sedative, without any specification as to age.

If we have any fault to find with this book, it is that there is not enough of it; but we hope that the inevitable success of this volume will encourage the author to compile similar handy volumes on the treatment of the other organs of the human body.

PROCEEDINGS OF THE AMERICAN SOCIETY OF MICROSCOPISTS. Fifth Annual Meeting, held at Elmira, N. Y., August 15-18, 1882. Buffalo: Bigelow Brothers.

THIS volume contains a large number of papers, most of which represent original work, which is most creditable to the Society.

THERAPEUTIC USE OF THE FARADIC AND GALVANIC CURRENTS IN THE ELECTRO-THERMAL BATH, with History of Cases. By JUSTINE HAYES, M.D. Chicago: Jansen, McClurg & Co. 1877.

THIS is a small work, written three years ago. The author claims so much that we are left as doubtful about electro-thermal baths as ever.

QUIZ COMPENDS; A COMPEND OF HUMAN PHYSIOLOGY. Especially adapted for the Use of Medical Students. By ALBERT P. BRUBAKER, M.D. Philadelphia: P. Blakiston & Co.

THIS little volume of 133 pages is necessarily incomplete, and is not minutely accurate, but for the purpose of cramming students it will no doubt answer. We are inclined to think that for New York students it says too little about the nervous mechanisms.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, March 1, 1883.

FORDYCE BARKER, M.D., LL.D., PRESIDENT, IN THE CHAIR.

INTRA-UTERINE INJECTIONS.

DR. LAURENCE JOHNSON related the history of a case which illustrated the possible dangers of intra-uterine injections with Chamberlain's tube. He had practised the injections for about one week without any accident whatever, and the next time, introducing the tube with the utmost care, and throwing the current of water in with as near as possible the same force as had been previously used, he found, when the injection had been finished, that the water was tinged with blood, and some blood followed withdrawal of the tube. A severe chill occurred within half an hour, the temperature rose to 107° F., the pulse to 160, and this condition continued for two or three hours and then subsided, and the patient had since progressed very favorably.

The PRESIDENT remarked that within the past few years he had had occasion to frequently use intra-uterine injections, and to express a word of caution to those whom he had met in consultation in regard to continuing the use of intra-uterine injections in the treatment of septicaemia and puerperal fever beyond a certain fixed point of time. It was well known that the uterine sinuses were closed ordinarily within three or four days after labor. It had occurred to him to see cases where the evidence had been conclusive to his mind that the introduction of the Chamberlain tube, a most excellent instrument to be used when intra-uterine injections are indicated, has been continued too long, and that after the sinuses have been blocked up by the formation of coagula or the contraction of the uterine tissues, some of the channels have apparently been opened, and the absorption of septic material has followed, as proven by serious reinfection. Furthermore, it has been noticed that after using intra-uterine injections for one or two days, when the tube is withdrawn it has been found to be covered more or less with little points of blood, and in some cases slight hemorrhage has followed, and in others profuse hemorrhage has occurred. Consequently he had frequently spoken concerning this possible danger in continuing the use of the tube for such a length of time that it becomes a source of traumatic injury to the internal surface of the uterus, and thus of infection.

DR. ISAAC E. TAYLOR then read a paper on

THE NATURALLY FAULTY OR CONTRACTED PELVIS; WITH THE HISTORY OF A CASE OF LABOR, THE NON-DELIVERY OF THE CHILD, AND THE DEATH OF THE MOTHER, AFTER CRANIOTOMY AND CEPHALOTRIPSY.

The faulty pelvis referred to embraced the equally contracted or the justo-minor, the infantile or the immature, and the male or the funnel-shaped. The patient, whose history was given, was twenty-nine years of age, healthy, whom he first saw in consultation with Drs. Wharton, E. A. Judson, Waterman, and others, on July 28th. At that time the pains were short and recurred at intervals of ten minutes; the os was dilated to about the size of a half-dollar, and the head occupied the left occipito-anterior position. Ergot produced only a very slight increase of pain. A third of a grain of morphine was then administered hypodermically, and the patient got some rest. On July 29th the os was found widely dilated, the head occupying the same position as before and resting at the brim. Forceps were applied, but no change could be effected in the position. Version was then attempted, but was unsuccessful. Craniotomy was then performed, and at that time the position of the head was transverse, and at the superior strait with the

brow presenting, and perforation was made on the right side. The cephalotribe was applied, the handles brought into position, and the brain more freely evacuated, and then traction was made for fifteen or twenty minutes without causing any advance. The instrument was then removed, and on examination it was found that the cranium had regained the same form as before its application, and this Dr. Taylor believed to be not unusual. He then applied his long narrow-bladed forceps, and brought the head more securely into the pelvis. A right-angled blunt hook was inserted into the mouth of the child, and Meigs' long embryotomy-forceps were applied, and the head brought into the inferior strait, and finally delivered after three hours' trial. The shoulders then offered an obstruction, and on examination he became convinced that the pelvis was naturally faulty, or equally contracted, and there was not sufficient space to permit any further manipulation by the hand. A right-angled blunt hook was introduced, and firm traction made, but no change in the position of the shoulders could be effected. During all this time the patient's general condition grew worse and worse, despite hypodermic injections of brandy and other measures, and she died undelivered after three and a half hour's faithful trial.

This form of pelvis, the equally contracted, he believed, was much more frequently met with than is generally admitted, and that it should receive as much consideration as those forms which depend upon certain general conditions, such as rachitis, malacosteon, etc. The infantile or immature pelvis is explained by an arrest of growth due to some important impairment of the constitution. For the equally contracted and the male pelvis no such explanation could be received. In the male pelvis, or the funnel-shaped, or the Irish pelvis sometimes called, a condition of advanced ossification exists, and indicates a healthy constitution. Barnes regards the equally contracted pelvis as due to the fact that the person is small, but Dr. Taylor believed that it did not necessarily follow that a female of small stature should have a small pelvis. With the exception of some German writers, the subject of equally contracted pelvis had scarcely been mentioned. Velpeau had once said that he had yet to learn that such pelvis ever offered an obstacle to successful parturition, but he soon afterward had an opportunity to become convinced to the contrary. The equally contracted pelvis sustains a normal relation to the size of the body, and the woman having it has the same general structure, and does not differ from health, either in stature or general condition. No positive information can be obtained in regard to the existence of this pelvis until labor has somewhat advanced. The position of the head may assist somewhat. It may be oblique at the superior strait; the occiput may dip at the commencement of labor, and it should do so, for flexion is absolutely and positively necessary. Should complete flexion not take place, a brow presentation, or a face presentation, will usually occur. After delivery is completed some notion of the condition of the pelvis may be formed by the condition of the head, and the specimen presented gave an excellent illustration of this point. There was marked overlapping of the parietal bones, compression of the frontal bones, and a ball-like appearance of the cranium. Another means for determining whether or not this pelvis is present is pelvimetry. Dr. Taylor did not place much confidence in the various methods of measuring the diameters of the pelvis, and believed that internal pelvimetry could be best accomplished by the introduction of the whole hand. If the hand moves freely in the cavity of the pelvis, the diameter must be more than three and three-fourth inches. In measuring the outlet of the pelvis Breisky's method was most valuable.

With reference to treatment, the use of the forceps was almost totally impracticable. Should craniotomy have been performed, version might succeed. Should the child's head rest in the cavity of the pelvis and the case be seen early, he would perform Caesarian section; but if

not. he would resort to either laparotomy or symphysiotomy, and he was inclined to regard symphysiotomy as the more acceptable operation.

DR. E. A. JUDSON gave a *résumé* of the clinical history of the case reported by Dr. Taylor, described the successive steps of the craniotomy and the difficulty experienced in attempting to turn the child. A great danger in these cases, he thought, was liability to rupture of the uterus. The most interesting question, perhaps, was with reference to diagnosis; that is, whether there are any certain means upon which we may rely. He was inclined to think that internal pelvimetry might furnish something in this direction, and then referred to a method recommended by Carl Schroeder for obtaining the diagonally conjugate diameter, as he had called it. It consisted in introducing two fingers, allowing the tip of the middle finger to rest upon the promontory of the sacrum, and then note upon the index finger the point at which it came in contact with the inner edge of the arch of the pubis. This diameter being obtained, it bears a certain relation to the other diameters, and perhaps in this way a proximate estimate might be formed with reference to the condition of the pelvis. With reference to external pelvimetry it did not seem to be of much service. He thought that some information might be obtained by resorting to abdominal palpation early.
